BRITISH GAS

ENGINEERING RESEARCH AWARDS

British Gas has established a new scheme for postgraduate engineering awards for research in areas of value to British Gas. Up to 3 Engineering Research Awards will be made each year to support Ph.D or D.Phil research in engineering in universities or polytechnics in the U.K. This scheme is complementary to the existing British Gas Research Scholarships.

Of the Awards to be made in 1982, one will be for research in the general field of **HIGH DENSITY DIGITAL TAPE RECORDING.** This is an area in which British Gas has stimulated some important developments in recent years.

British Gas interests in this field include: –

1. Investigation of facets which influence the recording process; tape system dynamics, tape emulsion, head drive, design and properties of recording heads, wrap angle, head gap.
2. Consideration of data coding methods, data deskewing, data recovery, data compaction.
3. Data formatting, error detection and correction, data reduction.

Specific proposals are invited from university or polytechnic staff, which either relate directly to one or more of the above topics, or associated fields of interest in magnetic tape recording technology.

Attractive financial aspects of the Award include: a maintenance allowance comparable to a fully "topped-up" Science and Engineering Research Council CASE award (currently £3,830 for a student living in London); an equipment allowance for the Department of £1,000 adjusted annually to take account of inflation; a book allowance of up to £200; and an opportunity for the holder of an Award to make one technical visit abroad.

Proposals should be sent to the Manager, External Affairs, Research & Development Division, British Gas Corporation, 326 High Holborn, London WC1V 7PT, from whom further information may be obtained. Closing date for applications is 26th July 1982.

BRITISH GAS

Circle No.01 on Reader Service Card.

Journal of Microcomputer Applications

Editors in Chief: J.L. Alty and M.J. Taylor

Publication: Quarterly
Subscription: Volume 5, 1982
Full Rate: £30.00 (UK) / $ 79.00 (overseas)
Personal Rate: £15.00 (UK) / $ 39.50 (overseas)

From 1982 Academic Press will take over from Liverpool University Computer Laboratory the publication of the Journal of Microcomputer Applications. This international quarterly journal will provide a forum for all those involved in the applied areas of microcomputing, in university, industrial and commercial environments. It will report work carried out in the design, production and testing of microcomputer applications in all fields – computer control, data processing, telecommunications, networks, medical systems and others.
A novel approach of the journal will be its coverage of previously neglected software aspects, such as design techniques and the application of high-level languages on microcomputer systems. Papers on hardware will also be welcomed, for example on design, integration and testing of systems, interfacing problems and new devices. The journal will also include tutorial papers, letters and book reviews, and special sections will be planned to cover applications in particular fields, or investigate particular problem areas. Long or short contributions of the highest quality will be sought, and all papers carefully refereed. As it is very important that papers in this fast-moving field are published quickly, rapid publication will be a key aspect of this journal.

Sample copies available on request from ***Jane Lawrence, Academic Press Inc. (London) Ltd, 24-28 Oval Road, London NW1 7DX. Please quote reference JL/06.82/A108.***

Nature in Poland

Readers wishing to subscribe to a weekly copy of *Nature* on behalf of a colleague in Poland (where hard currency is scarce) should send a cheque for £50 (or the equivalent in any currency), accompanied by their name and address and that of the proposed recipient, to the *Nature* office in London or New York (see addresses opposite page 1). For further details, readers are referred to *Nature* 3 June, p.354.

Reading this book is a biological necessity.

The Growth of Biological Thought

Diversity, Evolution, and Inheritance
Ernst Mayr

This controversial, epic work is the first book ever to integrate biological thought with Western intellectual tradition.

Beginning with Aristotle, Mayr traces the development and maturation of the three central concepts of biology – classification of life forms, evolution of the species, and inheritance and variation of characteristics.

"No other book tells in such a lucid and critical way the evolution of ideas that led to modern biology." – François Jacob

"A masterly analytical and synthesizing history of biological ideas by a master biologist."
– Robert K. Merton

"This great book should be required reading for every biologist and for everyone interested in the history and philosophy of science." – I. Bernard Cohen

"It is a wonderful thing when the world's leading evolutionary biologist and a top historian collaborate on a book of such breadth and depth. In this case, they are both the same man, Ernst Mayr, and the result is wonderful." – Stephen Jay Gould

"Truly an extraordinary book."
– René Dubos

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.*

New from Napco®:

An autoclave engineered for the biotechnologist.

Step-saving convenience.
Completely portable unit goes anywhere. Plugs in standard 20 amp. outlet, requires no plumbing.

Timer measures only actual sterilization cycle.
New automatic precision timer starts running only after sterilization temperature is reached.

Fully automatic precision performance.
No attention is required by the operator through the complete sterilizing cycle.

Slow or fast exhaust cycle.
Switch to slow or fast exhaust cycle with the flip of a switch.

There's much more. Send for the new Napco autoclave brochure for complete information.

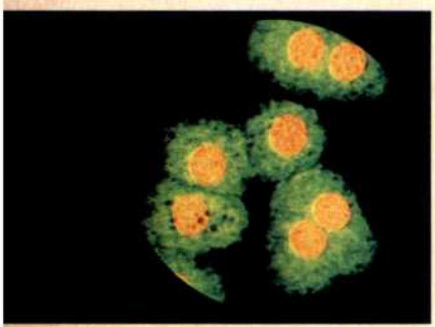
NIKON VISIONS



NIKON REVOLUTIONIZES OPTICAL PERFORMANCE WITH THE FX PHOTOMICROGRAPHY SYSTEMS.

CF UV-F 40X Rat liver cells

INSTRUMENTATION
Nikon's advanced UFX, HFX, AFX automatic exposure camera systems and PFX manual system.

SIGNIFICANCE
Nikon's exclusive FX direct projection design increases light transmission efficiency to greatly reduce exposure times, enhance lowlight metering sensitivity and dramatically improve image quality.

SPECIFICS
Nikon's remarkably affordable FX camera systems speed and simplify the photomicrographic process. High light transmission efficiency reduces typical exposure times by up to a factor of five. This is especially important for darkfield and fluorescence techniques.

To aid ease of operation, the models UFX, HFX, and AFX offer fully automatic microprocessor exposure control and LED digital exposure readout. Model UFX features a highly sensitive photomultiplier system with choice of 1% spot or integrated average metering, exposure memory and motorized 35mm film advance. Models HFX and AFX employ Silicon Photo Diode metering.

All Nikon FX Camera Systems adapt to 35mm, Polaroid, and 4×5 formats.

OPPORTUNITIES IN BIOTECHNOLOGY

for those with chemical, biochemical and molecular biology backgrounds

Vital information for anyone interested in biotechnology, whether BS, MS, or PhD. Genetic engineering company and career directory — a comprehensive, up-to-date summary of trends and employment opportunities in biotechnology. The Biotechnology Directory contans detailed, multifaceted information covering over 200 US and foreign firms. It includes names and addresses of contacts, descriptions of areas of research and projected research goals, summaries of past and present hiring trends, and the qualifications required for employment by each company. The Directory also provides concise background information on every company, from the largest public corporation to the smallest privately held firm.

Organized according to fields of application, the directory is divided into five sections: agriculture/animal health, chemicals/energy, human health, hybridomas, and pharmaceuticals. $25/section or $100 for all five. A more detailed financial and scientific directory will also be made available. For more information call (617) 734-8428 or write to:

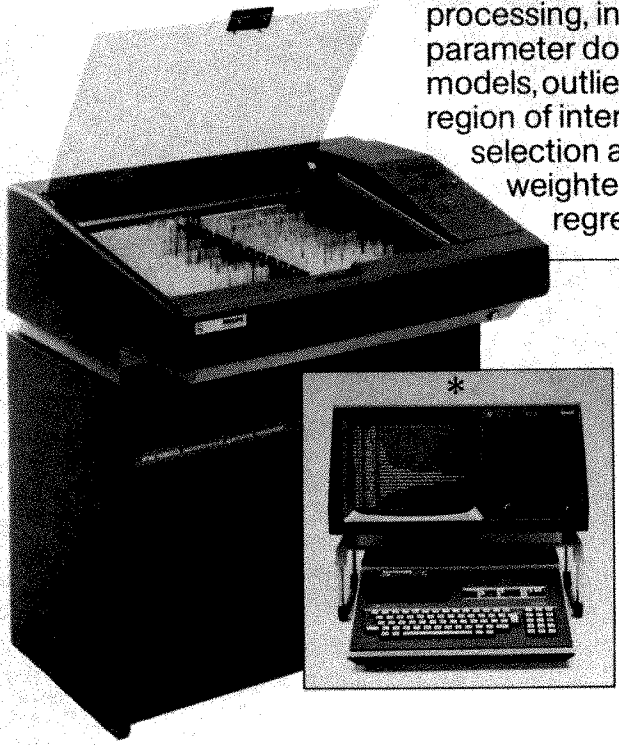
Take a closer look at what you get with a Philips gamma counter

- Spectrum scan and plot.
- Automatic recalibration.
- Sample capacity of 310, 480 or 620.
- RIA curve plot for single and dual label.
- Individually programmable sample trays (pioneered by Philips).
- Multi-user capability.
- Choice of detectors.
- User-oriented keyboard.
- Sample trays can be used in a centrifuge.
- Priority interrupt measurements.
- 15 Different measurement and calculation programmes (30 with optional personal computer).
- Sophisticated RIA data processing, including 4 parameter dose response models, outlier detection, region of interest selection and weighted regression.
- Choice of lead shields.
- Highly competitive price.
- Small, medium or large volume samples.
- Refrigerated and ambient systems.
- Service and spares availability guaranteed for at least 10 years.
- Remote control and additional data processing through the use of an optional personal computer.*



And that's just an introduction to the Philips AGC. Full details are described in our brochure. Contact your sales representative or drop us a line and we'll gladly send you a free copy.

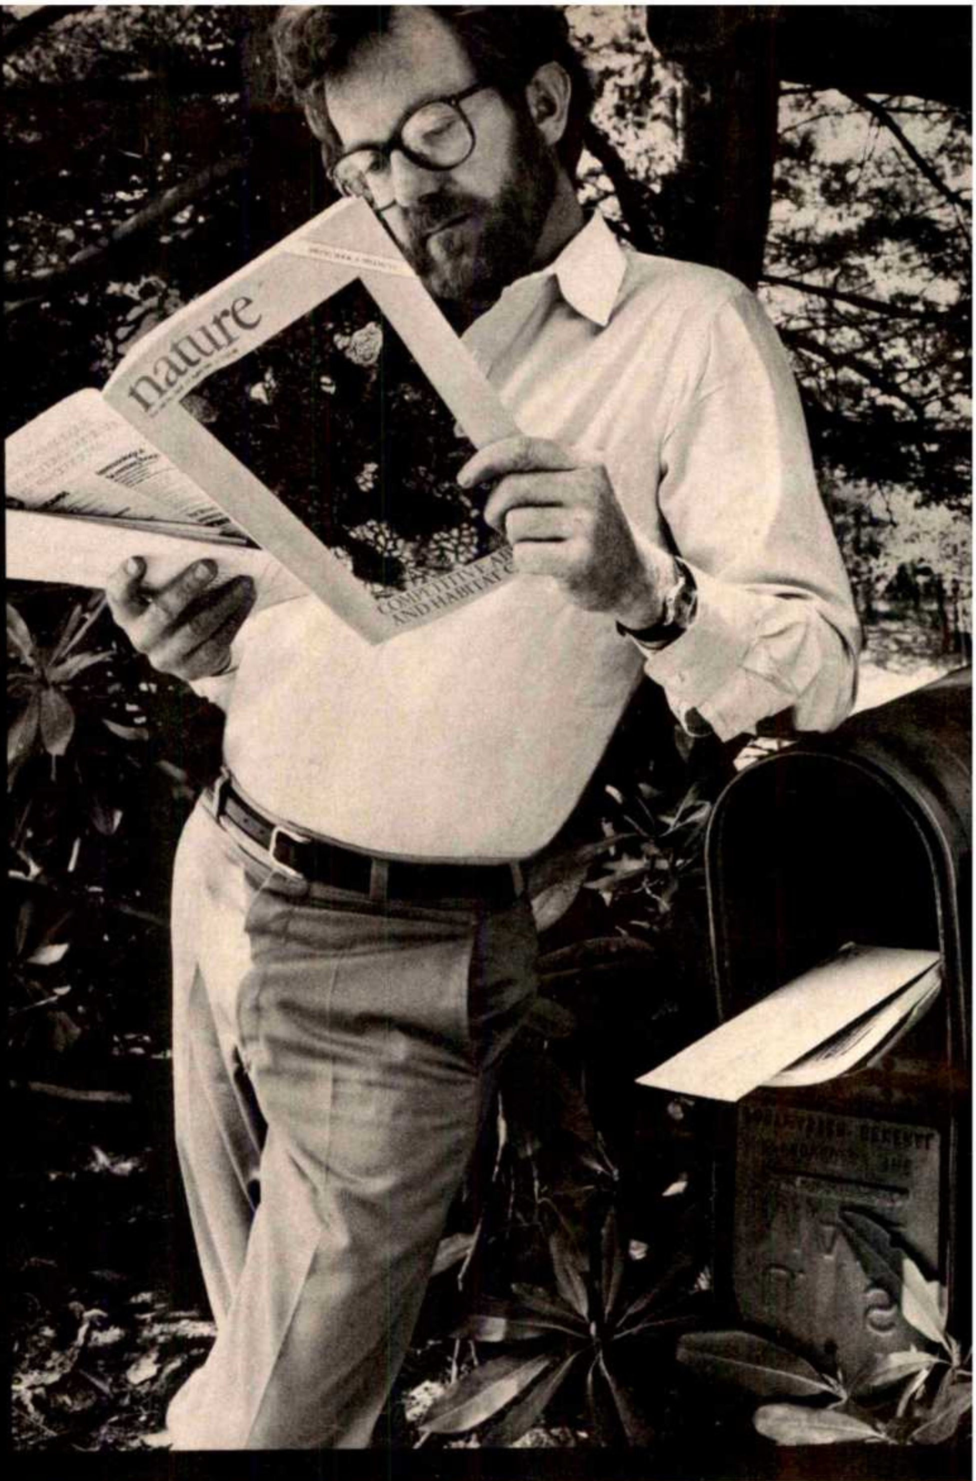
Nature in Poland

Readers wishing to subscribe to a weekly copy of *Nature* on behalf of a colleague in Poland (where hard currency is scarce) should send a cheque for £50 (or the equivalent in any currency), accompanied by their name and address and that of the proposed recipient, to the *Nature* office in London or New York (see addresses opposite page **593**). For further details, readers are referred to *Nature* 3 June, p.354.

The world's leading scientists get it every week and so should you... at ½ price.



Scientists who are leaders in their ield and who get to reap the rewards of their achievements are among Nature's most eager readers.

And they are renewing their subscriptions to *Nature* in record numbers.

If, like them, you keep searching or ways to speed up your research, or if you're looking for advancement where you work, or are thinking of moving on to something more stimuating, how can you afford to be without your own personal subscription o *Nature?*

It's the most certain and consistent way to get the research results, news, opinion, and analysis you need, while hey're still fresh and can be applied most usefully to your own work.

With your own *Nature*, you'll be well ahead of the monthly journals whose reports often lag a year or more behind ours. And there isn't a science weekly anywhere that covers research developments in as many parts of the world, as fully and authoritatively, as *Nature* does.

The good news is that we've cut *Nature's* personal subscription rate n half and, to top it off, if you subscribe for a full year, we'll send you, free, a copy of *Nature's* new, annual *Directory of Biologicals*. Planned for all 1982, the *Directory* will be the first truly worldwide buyers' guide to biological products. It will be available only to yearly subscribers (or, for $45, to buyers of the hardcover version, in bookstores).

A personal subscription to *Nature* has never been more attractive. We urge you to clip and mail the coupon today. For credit-card orders only, **call toll-free now: (800) 824-7888. Ask for operator 130.**

In California: (800) 852-7777.
Ask for operator 130.

Two Outstanding Solutions From A Well-Known Name, Synonymous With Precision

In microscopy, what we see is of utmost importance. The sharper the detail, the better. And our findings should not only be visible through the viewing eyepiece.
We should be able to document them quickly, easily and accurately on photographic film. Olympus, a well-known name in precision instruments, now offers outstanding solutions to both needs. The BH-2 System Microscope and the PM-10AD Photo and Cinemicrographic System. A superb combination that features the latest optical, mechanical and electronic advances. And best answers the diverse requirements of microscopy and photomicrography today.

BH-2 MICROSCOPES

The Modern Scientists' Choice.

To satisfy different user applications, the new BH-2 System Microscope is available in three different configurations.

Model BHS microscope is best suited for research and demanding clinical applications. It accepts a wide variety of modular accessories to ensure the highest system performance possible. A highly sophisticated model, it is perfect for photomicrography.

Model BHT microscope is suitable for research and training purposes. Space-saving and easy-to-handle, it features the same choice of accessories as the BHS.

Model BHTU microscope is especially effective for routine laboratory applications where observation of numerous specimens is required. It assures smooth handling and marking of all specimens.

LB OBJECTIVES

Indispensable Value That Makes The BH-2 Top-Of-The-Line.

Olympus is proud to offer a newly-computed series of LB (long barrel) objectives which offer increased working distance and the utmost in resolution, contrast, image clarity and flatness of field. In conjunction with the new 10x viewing eyepiece, these objectives provide a visual field of 20, the largest available for a conventional microscope.

What's more, a completely new and unique illuminating system permits Köhler illumination, even with 1x and 2x objectives.
In addition, 1x and 2x objectives are parfocal with 4x and higher power objectives.

PM-10AD

It Leaves Nothing To Chance.

The beauty of the PM-10AD Photomicrographic System is that it leaves no room for error. A built-in microcomputer ensures quick, accurate and fully automated photographic and cinematographic documentation. Exposure, 35mm film transport and compensation for reciprocity failure are completely automatic. A complete selection of film formats and other advanced features are provided. Thanks to the clearly readable LED digital display the programming and monitoring of various functions, e.g. time-lapse photography, can be performed with a minimum of effort and experience.

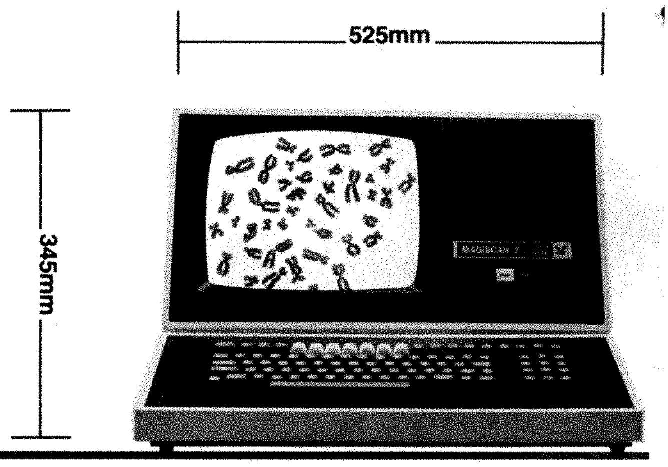
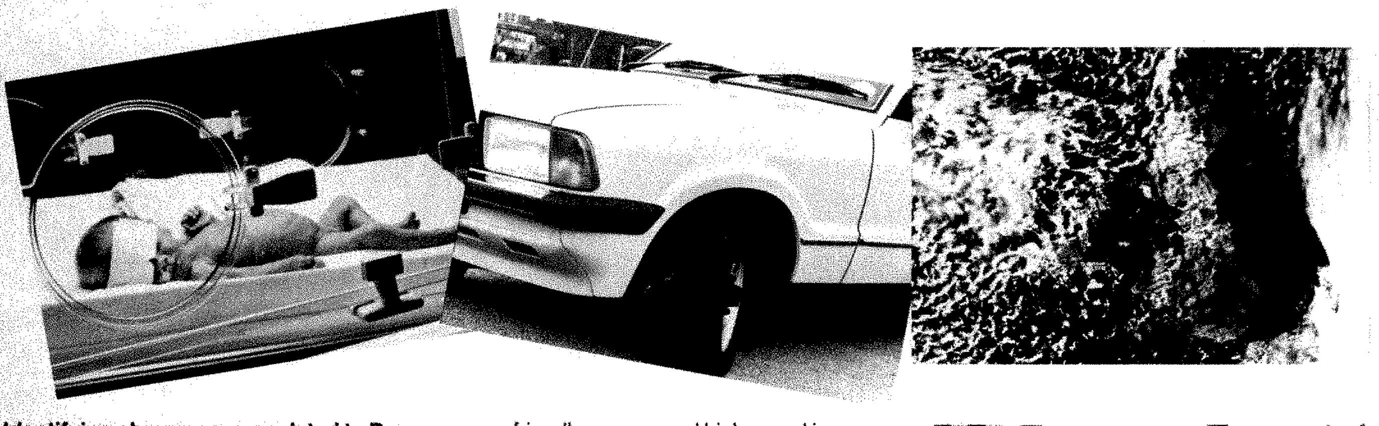
No other image analyser offers so much research capability in such a compact unit.





Identifying chromosomes related to Downs Syndrome in unborn babies . . . helping research into safer, more efficient tyres and brakes for the motor industry . . . analysing satelite photographs to help predict earthquakes . . .
. . . just three examples of the power and flexibility of the Magiscan 2 image analysis system.
The integrated hardware/software design of Magiscan 2 not only provides an extra large image store; ease of operation via interactive, user friendly menus, and high speed image and data processing, it also enables the complete package to fit into a desk-top unit, which occupies the minimum of valuable laboratory space.

If you want to count, measure or analyse images from optical or electron microscopes, photographs, films or real life objects, Magiscan 2 has the power and flexibility to provide reliable results . . . without taking over your laboratory.

1 July 1982

Should the Atlantic be widened?

Mr Alexander Haig's replacement as United States Secretary of State is not in itself remarkable; his successor's task is to head off the growing estrangement of the United States from Western Europe.

The departure of Mr Alexander Haig as United States Secretary of State will not be widely mourned; his vanity and impulsiveness ensured that even those governments elsewhere whose causes he supported were uneasy about his essays in diplomacy. But Mr Haig could hardly have chosen a more momentous time to resign. This week has seen the beginning of the Geneva talks on strategic arms between the United States and the Soviet Union, perhaps the most cheerful development on the international scene for a decade. But the meeting of the heads of governments of the European Community in Brussels this week will also have served to emphasize that relations between the United States and Western Europe are fast running towards the rocks. If Mr George P. Schultz, Mr Haig's successor, can find the time from what is bound to be his immediate preoccupation with the Middle East, he will put Western Europe at the top of his pile of problems. And he will conclude that there are two important conditions that his government must satisfy — that it must acquire a better understanding of what the European problem is and a literally more coherent way of dealing with it.

There are three main groups of issues to be ironed out — one military, one economic and one a mixture of economics and politics. The first, difficult enough, is the simplest. The United States resents what it considers to be the underspending by European governments on conventional forces and the unwillingness of some of them to provide hospitality for the intermediate-range nuclear missiles due to be installed from the end of 1983. The first complaint has substance and should be met, preferably by better planning of the mutual defence of Western Europe. The second complaint, understandable enough, overlooks the delicacy of the domestic politics of those Western European governments, perhaps all of them, dependent to some extent for their survival on voters who are unwilling to give house-room to other people's missiles without something in return. The United States is right to ask that those in Western Europe whom it is willing to help defend should share some of the risks but wrong to expect a favourable response while it was dragging its own feet on arms control. Mercifully, that stumbling block may now have been removed. Much will depend on what happens in Geneva. But the needless delay in embarking on these talks may already have helped to undermine Chancellor Helmut Schmidt's West German government (which, admittedly, has other than nuclear problems on its plate). The need all along has been for a fuller sense in Western Europe of having been consulted in the planning of mutual defence. Mr Schultz and Mr Caspar Weinberger, the United States Secretary of Defense, should bend their energies to that goal.

The economic problem is much less tractable, derived as it is from the pact between Congress and the Administration that the budget deficit should be allowed to run at $80,000 million or, probably, even more. The strictly domestic consequences of this development are predictable, but will be delayed. The inflation rate, now dramatically reduced to about 6 per cent a year, will either shoot up again within a year or the flickering promise of economic revival will be extinguished. Meanwhile, the United States is meeting its huge budget deficit by borrowing funds from overseas — the effect of the prevailing high interest rate that underpins the banking system, one of whose consequences is the strength of the dollar against other currencies. What is happening is the opposite of what happened in the late 1960s, when the Johnson Administration paid for the Vietnam war by printing dollar bills and thus exporting inflation. Now, by sucking in funds from the international banking system, the Reagan Administration is exporting deflation.

The consequences for the economies of Western Europe are already serious and much resented. But why should not the United States manage its financial affairs in the way that suits it best, putting up with the domestic consequences as they fall? For two reasons. First, it is no longer possible to separate international financial relationships from international relations generally. With the best will in the world, states in Western Europe thrown into recession by exported deflation will be less able than otherwise to modernize their armed forces and shoulder a full part in their own defence. But they will also be less easily persuaded to other desired goals if they are struggling to deal with domestic difficulties they believe with reason to be caused by the eccentric economic policies of the United States. And it cuts no ice to say that the US Federal Reserve, whose decisions determine interest rates, is constitutionally autonomous. Everybody knows that. But everybody also knows that the Administration is responsible for the budget deficit that makes the Federal Reserve behave the way it does. Second, and more sinister, there is mounting evidence that the United States is seeking the best of both worlds — the right to export deflation but also the right to avoid the consequences that should follow by restraining international trade. Congress and the Administration have embarked on a host of protectionist projects whose result could be to destroy the international monetary and trade system that has sustained us all these past several decades. Europeans in their present mood will go off on their own. Mr Schultz would be well advised to head them off.

The presenting symptom of the third group of urgent issues is the Soviet pipeline for the sale of natural gas to Western Europe (see *Nature,* 3 June, p.349). Arguments about this project have rumbled on for several months. The declared customers for the pipeline's product (France, West Germany and neutral Switzerland) have agonized about the strategic implications of buying Soviet gas, and have publicly decided that they should sign up. The United States, since the accession of Mr Reagan and the appointment of Mr Haig, has blown hot and cold about the implications. Washington has made no secret of its view that they were unwelcome, but has occasionally said that they must be stopped. Mr Haig appears to have made his way at the Versailles summit last month with his expressions of sympathy for the dilemma of European governments placed in this cleft stick. The Administration's decision on Wednesday last week that United States corporations must instruct their subsidiaries and licensees in Europe (and elsewhere) not to supply advanced equipment for the construction of the pipeline is nevertheless unseemly — and a sufficient cause for Mr Haig's resignation.

It is beyond belief that a government so well provided with lawyers can have perpetrated such a gaffe. Corporations registered as such in the United States do not set up overseas subsidiaries for the fun of it, but (rightly) for self-advantage. At some point in the development of their business, they calculate that the time has come when an autonomous overseas corporation would be a better source of revenue than a force of travelling salesmen living

0028-0836/82/260001 02$01.00

out of suitcases. Qualitatively, the benefits of separate incorporation vary. Sometimes there is tax to be saved. Sometimes, local incorporation provides access to public purchasing that would otherwise be denied. Whatever the reasons for separation, however, the subsidiary corporation becomes a legal entity in the locality in which it is incorporated, and thus subject to local laws. But what if the local laws do not allow that an overseas subsidiary of a United States corporation should tear up a contract because of some instruction from its head office sent retrospectively at the behest of the State Department? This is what is now being required of those with contracts for the Soviet pipeline. The chief result, of course, will be a rash of law-suits and of compensation payments (ironically in convertible currency of the kind that the Administration wishes to deny to the Soviet Union). Further ahead but longer lasting will be the impression left in the minds of Western European governments (and/or their voters) that the United States has slipped into the habit of behaving as if Washington's writ is unconstrained.

Thus the events of the past few days have cast a pall over Western Europe. For the past several years, it has been customary (but not always easy) to say that the defects of the then-current foreign policy of the United States were the consequences of the division of responsibility between the White House and the State Department that seems at last to have been the indignity that Mr Haig could not stomach. Each time this recurrent crisis has come round, another tranche of transatlantic loyalists has been lost to doubt, but European governments have usually buckled to and have been able to hold the line. Always, in the past thirty years, transatlantic cultural cohesion has proved to be a powerful cement. And in any case there has been no alternative to United States hegemony. But now the wind is changing.

Private funds can matter

The legend that foundations are now too small to exert an influence has been shown to be false.

Private foundations have become financially so much smaller than public sources of research funds that it is customary to disregard them. For what, the argument tends to be, can foundations hope to accomplish with their meagre funds when the more immediate threat is to the survival of institutions, the annual running costs of which tend to outstrip the capital resources of foundations? Fortunately, that gloomy inference is not as valid as simple arithmetic would suggest. The lie is neatly given to this canard by the imaginative grant announced last week by the Wolfson Foundation to the two British centres for research in tropical diseases, the London School of Hygiene and Tropical Medicine and the Liverpool School of Tropical Medicine. The circumstances are worth remarking.

Both institutions are relics of the days of what the British used to call Empire, founded as they were to safeguard overseas servants of the Crown from unfamiliar infections by insect-borne parasites of various kinds. Almost by accident, they became places at which physicians, following the precept that prophylaxis is preferable to cure, sought to work out ways of dealing with tropical diseases at their source. Inevitably, they became prominent among the centres, mostly outside the tropics, at which an understanding of tropical diseases was cultivated and cherished. With the passage of time and the collapse of Empire (or colonialism), they have been increasingly supported by agencies concerned above all that physicians and paramedical people from the tropics should have a sufficient training in the diagnosis and treatment of these infections.

From here on, the tale is muddied. It happens (again by accident) that the London and Liverpool centres are parts of the British university system, and that the British government has recently decreed that new overseas students should pay such outrageous tuition fees that they cannot afford to be educated. So, earlier in this academic year, it seemed as if the tropical medicine schools in London and Liverpool would be in serious trouble, deprived of students and then robbed of funds with which to pay members of their faculties.

The Wolfson grant to the two schools jointly will in the circumstances have a marvellous effect. At a cost of £3 million over five years ("chicken-feed" will say the public research councils) it should be possible to keep the core of each research faculty in being and to arrange that the research they do is at once more imaginative and more closely coordinated than in the past. There is talk of using genetic manipulation to make parasitic antigens, and of understanding the human genetics of susceptibility to parasitic infection. But the prospectus is open-ended. Plainly, it would have been impossible for any public research council to have made such a grant. Yet the chances are high that it will succeed, and that two distinguished centres of research will remain productive. If, anomalously, it should turn out that research in tropical medicine continues to be centred partly in developed countries such as the United Kingdom and the United States, what harm will be done by that? Last month, the European Parliament gave the European Commission a hard time because it had proposed spending part of its meagre research budget earmarked for development in developed countries. The Commission has a longer purse than the Wolfson Foundation, but is less well advised.

Riding for a fall?

The French minister for science and technology may be about to overreach himself.

M. Jean-Pierre Chevènement, minister of science and technology in the Mitterrand government, seems seriously to have blotted his copy-book. For the best part of a year M. Chevènement's inclinations towards the left of his party have been hidden by his devotion to the cause of social transformation by the beneficent, even lavish, support of research and development, but last week he chose to exceed his brief by speaking in public about the war in Lebanon. Worse still, he gave it as his opinion that President François Mitterrand should invite the leader of the Palestine Liberation Organization, Mr Yassir Arafat, to Paris. For his pains, M. Chevènement has been rebuked in the most humiliating way, by means of a statement issued through the President's press secretary to the effect that the President and his foreign minister, M. Claude Cheysson, have no immediate need of Chevènement's assistance. Even Chevènement's friends must be wondering what he is about, alienating his colleagues in the French government just when the final decisions are being made about the budget for next year.

First, the good news. Such is the commitment of the President and the government as a whole to the cause of science and technology as the harbingers of innovation and thus of the prosperity that will buy social transformation that the immediate consequences of M. Chevènement's little lapse are unlikely to be serious. With Chevènement's *loi* now through the Assembly, (see page 6), the chances are good that next year's budget will be protected. Whether the same can be said of Chevènement himself is another question.

While ambition is inseparable from politics, ambition that shows too openly is, paradoxically, mistrusted. In the past year, M. Chevènement has been admired in the true Latin sense of the word (*admirare* = "to wonder at") for the clarity and certainty of his promises and envied because nobody expects them to be delivered for several years, let alone during the reasonable tenure by a bright young minister of a single office. During the past few months, Chevènement has succeeded as well as he could have hoped in carrying his *loi* through the French Parliament, but not without making enemies. Now there is some anecdotal evidence that his attention has begun to wander. His recent speeches have been repetitive; during the debate on his bill in the Assembly last week, he confined himself to what he called "laconic remarks". M. Chevènement seems to be preparing himself for other pastures. He may find that they are less hospitable than he would like if he continues to alienate the Elysée and the rest of the leadership.

Waste in research services damned

UK laboratories lack incentive to save costs

A damning indictment of peripheral waste in British government research establishments was published earlier this week by Sir Derek Rayner, one of the Prime Minister's favourite businessmen and her special adviser on efficiency in government. The report, based on surveys of 19 establishments and concerned exclusively with services for the support of research, suggests that savings of about a fifth in annual budgets would be possible without jeopardizing quality.

The survey is one of several being carried out of efficiency in different parts of the government's business. It consists of a summary of the several separate reports linked together by Sir Derek's own generalizations. One of his central complaints is that in government establishments the cost of support services, ranging from cleaners and doormen to specialist workshops, is lumped together as a central overhead and not apportioned to separate research projects.

The essential failure, says the report, is that neither the provider nor the user of laboratory support services has clear authority and accountability for judging value for money. Rayner says that research establishments should be reorganized in such a way that identifiable research managers are responsible for the whole cost of their projects.

In passing, the survey has uncovered a variety of memorable sources of waste. One establishment was found to have ten deliveries of internal mail each day while the National Physical Laboratory near London maintained eight vehicles that each made less than one journey a month. At the government's Building Research Establishment, a staff of six storemen handled an average of 10 transactions each a day, while the Royal Signals and Radar Establishment was found to have a stock of 17,500 items of scientific equipment with an average age of 8.7 years.

The Central Veterinary Laboratory is reported to have been breeding rats at a cost of £30 a head when suitable animals could have been bought in for about £2 each. The Royal Aircraft Establishment at Farnborough provides itself with an air taxi service at a cost a third greater than commercial charges.

The report on the coordinated survey complains that the government research establishments hold that outside suppliers should be used only when the establishment is too busy or cannot meet the technical need. This, the report says, “is wrong and costly”.

Establishments also tend to be extravagant of land and buildings. The report says that the National Physical Laboratory could save £635,000 a year by giving up 200,000 square feet of floor space and that the Central Veterinary Laboratory should dispose of 245 acres of land now used for breeding animals uneconomically. The report points out that establishments as at present organized have no incentive to make savings of this kind.

The Rayner report also complains that establishments charge too little for services provided to outside users and so “give away . . . public money”. Some establishments provide research reports free of charge when they have a “commercial value”, others sell products whose cost of production has been underestimated and others undercharge for services “in order to win contracts”.

The cost of the bureaucracy itself seems to be substantial. In four establishments covered by the survey on which the report is based, the cost of checking invoices externally doubled the real cost of all the items purchased. But the gravamen of the report's complaint is that “the individual manager of a scientific project is not aware of or responsible for the actual costs of the support he consumes”. The report recommends that responsibility should be transferred to project managers.

The suggested savings on annual costs amount to 14 per cent of the budget now spent on support services within the 19 laboratories and would be made chiefly by shedding 1,518 support staff, or 19 per cent of the total now employed. The report also recommends the disposal of 270 acres of land, 450,000 square feet of accommodation and 200 vehicles, thus raising £6.65 million.

Ministers responsible for the laboratories concerned have apparently agreed in principle to the report's recommendations. Government departments will be performing similar scrutinies of other laboratories in the hope of finding similar savings elsewhere. The plan is to draw up “action plans” for streamlining the support services of individual laboratories by the end of the year. Much remains to be settled, however, not least the questions of how to shed posts and how to change the jobs of researchers so as to encompass greater management responsibility. The reactions of laboratories and staff unions will be eagerly awaited. **Judy Redfearn**

New prospectus for European lab

Substantial changes in the direction and style of research at the European Molecular Biology Laboratory (EMBL) in Heidelberg were being put to the laboratory's council earlier this week by Dr Lennart Philipson, the director-general chosen by the council to succeed Sir John Kendrew's inaugural seven-year reign.

The plans are the outcome of consultation between Philipson and the staff of EMBL and of an almost total lack of contact between the incoming and the outgoing directors-general — ending in a most unknightly deed by Sir John. There have inevitably been clashes within the scientific advisory committee on the extent to which EMBL should pursue a structural approach to biology.

In essence, Philipson's plans call for a shift in emphasis from structural biology towards cell biology, for concentration on fewer areas of research and for better integration of the costly instrumentation division with the laboratory's biological programme. Philipson also says that EMBL's outstations at Hamburg and Grenoble should grow and become more autonomous, and that the laboratory should increase its role as an international training centre, offering more technical courses and eventually a PhD programme.

Another of Philipson's plans is to replace the system of indefinite tenure for a few of the 250 of his staff with one of rolling tenure for up to a quarter of them. In practice, this will mean that those with tenure will always be on five years' notice. Philipson believes this to be the best way of retaining flexibility while attracting good scientists for short periods. Philipson says that in part this proposal is a response to an unexpected legacy inherited from Kendrew. As soon as he was named director-general in November 1980, he says, he asked that no additions be made to the four tenured staff without consultation either with himself or with the chairman of this council. Kendrew, however, afterwards endowed eight staff members with tenure, five of them within his last three months, without consultation. He was, it appears, quite within his rights to do so (but when asked earlier this week about his reasons refused to comment).

The intended difference in style of research in the next five years reflects a change in both time and directors-general. Whereas Kendrew encouraged certain biological themes at the laboratory, he was prepared to back individuals whose research was not closely allied to any one of them. Philipson, however, tends to the view that backing individuals was even then an outdated approach, and says that the modern need is for a team approach to major problems in biology. Philipson thus intends to concentrate the biological research of EMBL on membranes and on the process of differentiation. Membrane biology is the one area of research in which

0028-0836/82/260003-02$01.00

the laboratory has a high reputation. The work, however, has been mostly on mechanisms of transport across membranes, and Philipson plans to supplement this with a structural approach. As a start, he claims to have recruited a specialist Rosenbush from Basle, who has recently obtained some of the first ever crystals of a membrane protein, the structure of which will be worked out at EMBL.

The laboratory has much less of a reputation in differentiation, and Philipson's plans depend upon the recruitment of new staff. There may soon be a major project on the terminal differentiation of blood cells and later another on growth factors, but competition with other laboratories on differentiation in *Drosophila* is all ruled out. Other projects ruled out or resisted during planning include mobility within protein molecules, chromatin structure and protein folding.

Inevitably the emphasis on some areas of research will be at the expense of others. Whereas Kendrew felt it essential to have a foot in the door of neurobiology, Philipson will close the door. But Philipson, like Kendrew, is committed to instrumentation as a key to the success of EMBL, believing, however, that it should be better integrated into the research projects. About half of the laboratory's budget is spent on instrumentation, with the most advanced project that on low temperature electron microscopy designed to minimize damage to specimens.

The instrumentation division has also been essential to the unquestioned success of the synchrotron radiation outstation at DESY in Hamburg, where EMBL staff have been chiefly involved with building equipment for use by external collaborators. Philipson hopes to succeed where Kendrew failed by persuading the council to increase the staff at Hamburg from 17 to 25. He plans a similar increase at its neutron diffraction out station at Grenoble.

These plans are based on Philipson's appraisal that the outstations have done more than any other part of EMBL to justify its existence as a European laboratory able to engage in research that cannot be mounted nationally.

Both Kendrew and Philipson admit that such a description cannot be applied to much that goes on in Heidelberg, but Philipson emphasizes the increased role he intends for EMBL as a unique centre for training in molecular biology. It remains a manifest disappointment for many observers that the programme of research at Heidelberg is still much as it might be in any large well-funded national laboratory. And it could only justifiably be for that reason, monetary considerations apart, that Philipson might fail at the end of this year to get the 10 per cent budget increase needed to bring EMBL up to its full strength. **Peter Newmark**

Chemical weapons treaty

Talking again

Washington

The Soviet Union may be willing to accept some provisions for on-site inspections in a treaty banning chemical weapons. The first hint of Soviet movement on this issue — which has been the chief obstacle in US–Soviet negotiations on chemical arms — came in a speech on 15 June by Soviet Foreign Minister Andrei Gromyko to the United Nations special session on disarmament.

The United States broke off negotiations in 1980 on a treaty that would ban not only the use of chemical weapons, which is already prohibited by international treaty (the Geneva Protocol of 1925), but also their development, production or stockpiling. Soviet refusal to accept any on-site inspections and the Soviet invasion of Afghanistan were cited at the time as the reasons for suspending the talks.

In his speech, Gromyko said that a chemical arms treaty should provide for "a possibility of carrying out systematic international on-site inspections", of the destruction of existing weapons and of the continued limited production of toxic chemicals that would be permitted for defensive research purposes under a treaty.

The US State Department is officially saying only that it is studying the proposal and that it is too early to comment. The State Department is apparently wary of showing any favourable response until it can assess the substance of Gromyko's statement. The Soviets may elaborate on their proposal at the international disarmament conference which convenes on 20 July in Geneva.

A State Department official did say, however, that the Soviet proposal appears to address at least two of the three concerns the United States has been pressing — inspection of stockpile destruction and inspection of the permitted research production. The third area is inspection of the shut-down and elimination of existing chemical arms facilities.

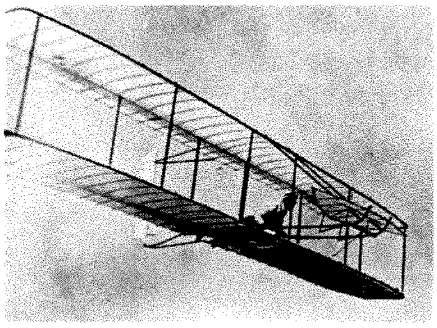
James Leonard, who was the US representative at the Geneva disarmament

Industrial secrets still in demand

Washington

The arrest of 18 Japanese businessmen in the United States last week on charges of conspiracy to steal confidential computer information from International Business Machines Corporation may really have been just the latest instalment in a long tradition of international technical espionage. According to Professor Alfred Gollin, a historian at the University of California at Santa Barbara, it now appears that at least two self-appointed spies kept tabs on Wilbur and Orville Wright and reported to the British military.

One was C. S. Rolls (of the automobile company) who in 1908 wrote to the British Committee of Imperial Defence offering to go to France and "draw out" the Wright Brothers. Rolls also bought a Wright biplane, which he offered to put at the disposal of the government. For several years before, the Wrights had negotiated with the British on a sale of their planes, but the deals repeatedly fell through.



The other unofficial spy was Patrick Alexander, an active member of the Royal Aeronautical Society. He first visited the Wrights in 1902, a full year before their first powered flight, and apparently became quite friendly with them. Professor Gollin found that, for a private citizen, Alexander did have unusual entrée into government circles. This included a close working relationship with the secret Balloon School and with a key figure in the British army's aeronautical programme.

But Alexander also demonstrated the pitfalls of leaving the job to amateurs. He was actually invited by the Wrights to Kitty Hawk to witness their first flight on 17 December 1903, but went instead to the St Louis Exhibition — this was when world's fairs were still worth going to, no doubt.

The Wrights later became convinced that Alexander was in fact a spy. But by that time, the Wrights were embroiled in a patent fight and, according to Dr Tom Crouch of the National Air and Space Museum in Washington, "they thought everyone was spying on them".

In fact, says Dr Crouch, "they developed a conspiratorial mentality themselves", going so far as to send their younger brother, Lorin Wright, to spy on Glenn Curtis, their rival. In what became another amateur performance, Lorin simply marched into Curtis's factory and began taking pictures until he was discovered and had his film forcibly and prematurely exposed by a Curtis employee.

Dr Crouch suggests that any spying that did go on was motivated more by the commercial interests of individuals than the military interests of governments. On the other hand, Edwardian England clearly did have its worries about the Wrights' invention. "The story is not that man can fly", said a British newspaper publisher at the time, "but that Britain is no longer an island". **Stephen Budiansky**

0028-0836/82/260004-02$01.00

conference from 1969 to 1971 and who is now with a pro-arms control group called the Committee for National Security, says that although the Soviets are clearly making political hay out of the proposal, it is nonetheless more than just words if experience is any guide. "They know that if they make a statement like this, they will eventually be called on it", he says.

Stephen Budiansky

French universities

More change

Paris

The French universities are to be reformed — again. A couple of years ago, the then President Giscard D'Estaing's minister of universities, Mme Alice Saunier-Seïté, set about the universities with a hatchet, amputating this and that to academic screams of "Fascist!" and worse. But now, more quietly and more carefully, the present socialist government of France is setting about a similar task. According to present analysis, Mme Saunier-Seïté was right about many things — it was only her draconian methods that were wrong.

The socialist idea is to base change on a 130-point questionnaire sent out a few months ago to presidents of universities, engineering schools and other such establishments by M. Claude Jeantet, cabinet member at the ministry of national education. The questionnaire was very far-reaching: it encouraged respondents to redefine the role of higher education in France. Jeantet has just analysed the results of that questionnaire — and he will use them to prepare the text of a new law on French higher education for his minister, M. Alain Savary. The new law is promised for the autumn. Although Jeantet will not publish the figures until then, it is already emerging that the government's task will be aided by a remarkable and sudden change in social outlook in the universities — one that has surprised even Jeantet. Now, university staff, often regarded in France as left-wing, see the government and even industry as partners, rather than enemies as appeared to be the case under Giscard d'Estaing. Now, it seems from the questionnaire, the universities are ready to forge links with industry and to run more courses aimed at training students for productive employment — an area in which they have previously been weak. It seems that one remnant of the 1968 university rebellion — a horror of the market-place, and of all government control — is being replaced by a nationalistic commitment to help France escape from the present economic crisis. According to Alain Geismar, one of the revolutionaries of 1968 and now vice-president of the University of Paris VII, the universities are now preparing to consider the provision of continuing education, post-retirement courses and science shops on the Netherlands model.

Behind a broad willingness to change in the universities, however, a number of difficult issues lurk. For example, one of the hottest and perhaps most important for French science is the reform of the French PhD system, presently a two-step exercise which is both weaker and stronger than an American PhD. The weak step is the more contentious: the troisième cycle (essentially a two- or three-year MSc course). A good result in the troisième cycle is enough to get a graduate an effectively tenured post as a researcher (assistant at a university, or attaché in a government laboratory). The second step — the major thesis, leading to a doctorat d'état — can take seven years.

Science minister Jean-Pierre Chevènement's law for research and technology, in its present form, contains a commitment to change the system, but no details about how it is to be done; that is up to Jeantet and Savary.

Tenure is, however, a very closely regarded right in France, and the unions, whose influence over the government is strong, will defend it vehemently. One University of Paris professor, whose left-wing leanings combined with a desire to see France do good research perhaps make him typical, said last week that he was "schizophrenic" over the issue. The French system leaves a large pool of relatively untalented researchers at work in France, half of whom would not be in research if they were in the United States.

Robert Walgate

Argonne prepares for change

Washington

Argonne National Laboratory is renouncing a 16-year old agreement with a consortium of some 30 universities that has governed the laboratory ever since its principal machine, the Zero Gradient Synchrotron (ZGS), was built.

The laboratory outside Chicago is one of several, large, multipurpose energy laboratories whose fate is being deliberated by the White House and the Energy Research Advisory Board of the Department of Energy (DoE) (see *Nature* 6 May, p.3). Rumours that Argonne was to be closed helped prompt the move to change and streamline the laboratory's management. The ZGS itself was turned off a few years ago, leaving the laboratory to carry out other energy studies and nuclear physics, as well as some biology and other basic research.

Back in the heyday of building machines for high-energy physics, many colleges in the middle of the country wanted to have a big machine. When it was decided to put it near Chicago, a compromise was effected, in which other universities in the region could make input, and help get their scientists onto the machine, through a management group, the Argonne Universities Association (AUA). AUA's main job was to coordinate the high-energy physics programme at Argonne, but it also had management responsibility in other areas. The University of Chicago was also involved in management, through a tripartite agreement involving the university, AUA and DoE, which provides 90 per cent of the laboratory's budget of $200 million.

Without the ZPG, however, there is no need for regional high-energy physics co-ordination at Argonne. As one scientist formerly at the laboratory says, the AUA structure is also potentially divisive, allowing almost anyone who wants to do something to Argonne to get into the act.

So Argonne's management will gradually be streamlined. AUA will bow out and the University of Chicago will become the manager. Regional universities can still participate through an advisory steering committee. DoE will continue to fund the laboratory.

The laboratory seems unlikely to go out of business, according to DoE, but it may be substantially redirected. For instance, Senator Charles Percy wants to bolster the laboratory's flagging mission by transferring civilian research activities now at Los Alamos and Livermore laboratories to Argonne.

Deborah Shapley

Franco-Soviet space-flight

Up and away

The space-flight of the Frenchman Jean-Loup Chrétien, the first West European in orbit, has been hailed as a triumph for détente and cooperation in both France and the Soviet Union. Although events in Poland had moved a number of French scientists to sign petitions advocating withdrawal from the flight, the Centre National d'Etudes Spatiales (CNES) says that Chrétien's is merely the logical next step in a cooperation programme that has been flourishing for fifteen years.

The coincidence of Chrétien's flight and the final test-run of the US shuttle prompted *Le Monde* to draw a contrast between the French approach and the "cold-war" aspects of *Columbia.* (The fact that, in spite of frequent official denials, the Soviets also appear to be working on a shuttle with, presumably, a similar military potential, was overlooked.)

In their run-up to the flight, the French have exercised considerable tact, even coining the word "spacionaute" to avoid using either the American or the Russian terminology. In return, the Soviet side has permitted a degree of openness about the preparations for the flight that has not been seen since the preparations for the Soyuz-Apollo flight in 1975. While some of this

0028-0836/82/260005-02$01.00

must have been unavoidable, some revelations seem to have been made purely as an exercise in détente. Five days before the flight, for example, Professor Igor Konstantinovich Bazhinov, the deputy chief of flight ballistics, admitted on Moscow radio that Salyut-7 had undergone unexpected orbital drift, and that a special correction had been necessary to ensure the successful docking of the "international" crew — a degree of intimacy with his audience that is unusual by Soviet standards.

The French experimental programme for the flight was, in fact, outlined in the CNES annual reports for 1980, and includes sensory physiology (including the vestibular, visual and kinaesthesic systems) and the effects of soft radiation on the developmental capacities of unicellular and multicellular organisms. The biological experiments are a continuation of previous Franco-Soviet work using unmanned probes.

Little has been said, however, about the type of space station to be visited by the "spacionaute". Although all CNES releases spoke cautiously of a "Salyut" station, without giving it a number, they were illustrated by a schematic diagram of Salyut-6. Only after the launch this spring of Salyut-7 was it stated that Chrétien would pass his historic week in space aboard what the Soviets say is a more advanced and more confortable space station. **Vera Rich**

French science *loi*

Who will lose?

Paris

The long-awaited French law for science and technology, which guarantees a 17.8 per cent annual real growth in government civil research spending until 1985, is now almost on the statute books. At present, it lies under the harsh light of an inter-house committee of the French Parliament, which is attempting to reconcile the differences between the views of the Senate (which all but overturned the law) and the Assembly (which supported it). Second readings are to take place next week but it appears that the law will sail through much as planned by M. Jean-Pierre Chevènement and his team, even if those most affected will be reading its provisions with a magnifying glass to see exactly what has, and what has not, been left in.

One thing that was left out is causing the more cautious of French scientists to pause for thought. The law is divided into three sections: an introduction, the law proper (which is quite short) and an annexe. The full force of law attaches only to the law proper, so one question has been what is to go into the law, and what into the annexe? In the research ministry version, fundamental science is mentioned only in the annexe — where there is talk of 13 per cent growth (less than the 17.8 per cent total growth, reflecting the fact that the Chevènement plan mostly concerns technology). Some deputies at the Assembly, briefed by university researchers, pushed for the 13 per cent to be inscribed into the law proper, but the government refused.

Does this mean that basic research is going to be less well protected against the current French financial crisis than technology? Some French scientists fear so. The question is how far should Chevènement's technological imperatives, outlined in seven major investment programmes from space to biotechnology, encroach on and influence the whole of science. It is beginning to look as if they will be very pervasive.

For example, new accounting methods are to be applied to the big government research organizations, such as the Centre National de la Recherche Scientifique (CNRS), which means that they will be controlled from the ministry, programme by programme, rather than by total budget. The organizations will also be given explicit new tasks, such as the application of their research to profitable ends.

Even the small protection given to basic science by the ministry of national education may be being eroded, as the ministry appears to be adopting the same priorities as the ministry of research. (In distributing its research money, which amounts to perhaps a fifth of the total obtained by universities, the ministry of national education recently asked universities to favour groups already supported through the ministry of research and technology.)

Nevertheless, the fears may be misplaced if French research is compared with the situation of research in other countries. If the 13 per cent figure is respected — and ministry of research officials insist that although only in the annexe, the figure has force — French scientists will be doing far better than their foreign colleagues. For the sum includes a 4.5 per cent annual increase in the number of salaries, and salaries amount to more than two-thirds of basic research costs. The result is that next year's true research budget — what a laboratory director will have in his pocket to spend — would be up by more than 25 per cent in real terms, an increase so large that one senior researcher said last week that it would be "frankly a problem" working out how to spend the money.

For the ministry, the next problem will be how to raise the money promised, against a sombre French economic background (although the promised figures are only averages to 1985) and then how to put into effect certain structural changes outlined in the law. Not least of these is the reform of CNRS and related organizations which will be given new statutes allowing them to make profitable links with industry. CNRS will also get new rules for electing its internal review body, the Comité National. These new rules are themselves contentious. It appears that the Comité will exclude university lecturers not at present or previously associated with the organization, thus, according to some, deepening the rift between the universities and CNRS. **Robert Walgate**

Laboratory animal welfare

Congress in sight of compromise

Washington

After months of negotiation between animal welfare groups and representatives of the biomedical research community, a bill that would tighten up standards for the treatment of laboratory animals has reached the House of Representatives Science and Technology Committee.

This compromise proposal (HR 6245) is now the only serious contender among the several animal welfare bills filed with the House. It will be taken up by the committee later this month when the House returns from its Independence Day recess. The bill avoids some of the extreme measures that some animal groups had pressed for, such as setting aside up to 50 per cent of the National Institutes of Health (NIH) funds now going to work involving animals used for research into non-animal substitutes. But it would impose strict requirements on the care of animals used in federally-supported research. Researchers would have to justify any distress caused to a research animal and ensure that pain was minimized (through the use of tranquillizers and anaesthetics, for example). No animal could be used in more than one major operative procedure, except in special circumstances.

The legislation grew out of hearings held last autumn by a House subcommittee in response to considerable public pressure. At that time legislation for the protection of laboratory animals was not serving the interests of anyone very well. Under the present law, the Animal Welfare Act of 1966, the responsibility for enforcement falls on the Department of Agriculture (USDA), which critics say is understaffed and cannot do a proper job.

Last autumn, for instance, USDA inspectors found only minor violations in Dr Edward Taub's laboratory just weeks before he was indicted under Maryland's animal cruelty law for causing pain and suffering to monkeys. Although Dr Taub protested that he was the victim of a public relations stunt by a group called People for Ethical Treatment of Animals, which had infiltrated one of its members into Dr Taub's Institute for Behavioral Research in Silver Spring, Maryland, he was convicted of the charges and also had a $200,000 NIH grant taken away from him. Dr Taub appealed against the conviction, and his case is now being heard.

In an effort to obtain the widest possible support for new legislation, the subcom-

0028-0836/82/260006-02$01.00

mittee staff consulted groups such as the American Physiological Society and the Association of American Medical Colleges when drafting the bill, as well as animal welfare groups such as the Humane Society of America. The bill was reported out of the subcommittee on 9 June by a 14–1 vote.

Universities still have two strong objections, however, that may be raised in the full committee and may prevent any action being taken. One is that the standards set by the bill are quite high. For one thing, the new legislation would apply to rats and mice, which were exempted from the Animal Welfare Act. (Farm animals would continue to be exempt under the new bill.) Research facilities would also have to be accredited by an organization such as the American Association for the Accreditation of Laboratory Animal Care (AAALAC), which since 1965 has certified about 400 facilities under a voluntary programme. Universities claim that it would cost $500 million to bring the remaining NIH-supported universities up to the very high AAALAC standards.

This objection may be answered in part by a 10-year phase-in provision, which the subcommittee staff says should allow much of the upgrading (installation of new ventilation equipment, for example) to be done in the course of routine laboratory modernization and repair.

The second objection is that research facilities will have to set up animal studies committees and in particular will have to appoint one member from outside the university who is "primarily responsible for representing community concerns regarding the welfare of animal subjects". The committees would act much as human experimentation review committees do.

Balancing these possible objections, however, is an apparently growing recognition by the research community of the benefits that mandatory regulations will bring in terms of public reassurance — much as the recombinant DNA guidelines provided what one scientist calls an "umbrella of trust". This may be especially important now that the effectiveness of the Animal Welfare Act and the essentially voluntary system have been called into question.

US science societies

Women's rights boycott shadow

St Louis

Although the Equal Rights Amendment (ERA) to the US Constitution has now failed, many states will continue to be deprived of important scientific conferences for years to come. And it is possible that some societies will continue to boycott the fifteen states that dragged their heels on the amendment.

The amendment would have added to the constitution an interdiction of discrimination on the grounds of sex. By the extended deadline of 30 June, however, only 35 of the required 38 states had ratified the amendment, which thus becomes a dead letter.

The boycott was first organized in 1977 by the National Organization for Women (NOW), the most prominent feminist organization in the United States. Convention promoters in non-ratifying states have admitted they lost millions of dollars' worth of business during the ERA boycott. Convention sites in ratified states and Canada benefited.

How societies will respond to the lapsing of ERA is not yet clear. Some have abandoned the boycott, but others with large numbers of women members or which are otherwise committed to equal rights for women and minorities are ambivalent about giving their convention business to non-ratifying states.

The scientific societies that adopted the NOW boycott, and avoided Missouri, Illinois and some southern states none of which ratified ERA (see box), include the American Association for the Advancement of Science (AAAS), the American Society for Cell Biology, the Society for Neuroscience, the Society for Developmental Biology, the Endocrine Society, the American Astronomical Society and the Biophysical Society. But AAAS stresses that its policy on meetings is independent of NOW's boycott.

No complete list of boycotting societies exists, but if the experience of Professional Associates of St Louis is typical, fewer than half of all scientific organizations supported the boycott. Professional Associates handles convention planning for nine science groups, of which three supported the boycott. Of those three, two decided to drop the boycott in booking meeting sites after 30 June.

NOW itself has not decided whether to keep the boycott going past the deadline, but the question is likely to come up at its board meeting in July. Even if NOW formally ends the boycott, it will affect where organizations hold meetings for several years if only because many societies make their meeting plans years in advance.

AAAS, the Society for Neuroscience and the American Psychiatric Association are booked only in ratified states until the end of 1986, the Biophysical Society until 1985 and the American Society for Cell Biology until 1984. The boycott excluded some of the most popular convention sites in the United States such as Atlanta, Chicago, New Orleans, St Louis, Kansas City and Las Vegas.

Some other societies did not honour the boycott only because it was logistically too difficult. The Federation of American Societies for Experimental Biology (FASEB), for example, says it would have liked to have supported the boycott but "The federation's meetings are so large — 15,000 to 20,000 people — we require 50-60 simultaneous meeting rooms. Only one or two cities in ratified states can provide that." The FASEB meeting was held this year in New Orleans in Louisiana, which like most other southern states has not ratified ERA. But two of the six member societies of FASEB, the American Society of Biological Chemists and the American Association of Immunologists, do honour the boycott when they meet as separate groups.

AAAS acknowledges that it has been inconvenienced by its stand, especially when it switched its 1979 meeting from Chicago to Houston in order to hold the meeting in a ratified state. "It's always inconvenient to move a meeting in less than a year's time. We had to be in several different places in Houston." AAAS meetings can draw 4,000 to 8,000 people.

Non-ratifying states

The 15 states that did not ratify ERA are: **Alabama, Arizona, Arkansas, Florida, Georgia, Illinois, Louisiana, Mississippi, Missouri, Nevada, North Carolina, Oklahoma, South Carolina, Utah, Virginia.**

Germal Sanderson, vice-president for sales of the Chicago Convention and Tourism Bureau, acknowledged that cancellation of business meetings had caused "significant losses". He estimated that 23 groups cancelled previously scheduled meetings, costing the city more than $11 million. The effect of the ERA boycott could last until 1989, he said.

Nobody knows if the boycott helped or hurt the movement to ratify ERA. People representing boycotted convention areas agree that it did not help the ratification effort and may have hurt it.

Jim Hutchinson, director of convention sales for the New Orleans Convention Bureau, says "It was ridiculous to begin with. It inconvenienced a lot of people and not another state has ratified since it started". NOW itself does not know if the boycott swung any legislators' votes its way. "It certainly was effective in terms of dollars lost" says Judy Murphy, NOW press secretary. "But if it helped, it was just one or many things we did."

CORRESPONDENCE

Falklands story

SIR — The history given by Asociacion Argentina Para el Progreso de las Ciencias (*Nature* 10 June, p.450) is in error.

The islands were discovered by the English navigator John Davis, inventor of the backstaff and double quadrant, in 1592. Hawkins was there in 1594.

Commodore Byron took the islands for England in 1765 on the basis of this prior discovery and when the naval garrison was withdrawn in 1774 it left a plaque claiming full sovereignty and allowing Spain to maintain its settlement until 1806.

In 1816 the new United Province of Rio de la Plata having overthrown the Spanish yoke claimed to succeed Spain and a local governor was installed by them in the Falklands in 1828. In 1833 Britain expelled the Argentine soldiers and again raised the Union Jack in the Falklands.

The British prime minister said in 1834 that the British were not prepared to permit any other state to exercise a right as derived from Spain that Britain had denied to Spain herself.

The present conflict does not have its origin in Grytviken, but in the recent naked aggression by Argentina. What was said in 1834 by the British prime minister still stands.

Burning question

SIR — Most cosmologists feel that the evidence currently available suggests that the Universe originated with a big bang and is now in an expansion phase. One of the more important questions presented by such a scenario is whether or not the Universe will recontract to its primordial super-massive germ. The physical evidence required for resolution of this issue is not yet available.

There is, however, a source which provides the answer clearly and unequivocally. In II Peter 3; 10 it is stated: "But the day of the Lord will come as a thief in the night; in the which the heavens shall pass away with a great noise, and the elements shall melt with fervent heat, the earth also and the works that are therein shall be burned up."

Whence high IQs?

SIR — In *Nature* of 20 May, A.M. Anderson in his comments[1] on the article in the same issue by R. Lynn entitled "IQ in Japan and the United States shows a growing disparity"[2], refers to the increase in educational opportunities in Japan since the 1930s, perhaps implying that this increase might be partly responsible for "the Japanese IQ increase", even though Lynn argues against it. While agreeing with Anderson that no intelligence test can be totally culture-free and, therefore, the performance in any such test cannot be unreservedly taken as a true measure of a person's intelligence[3], I suggest that what has been found in Japan may indeed be true of all countries where a large proportion of the population has been deprived educationally and socially, over many generations and where people have overcome this deprivation through rapid democratization of education.

Where opportunities for education and access to knowledge and information, have been limited, education (or lack of it) tends to run in families, with only an extremely small proportion of either class (the educated or the educationally deprived) changing over to the other class. In India, for example, I estimate that education is a hereditary prerogative of between 12 and 20 million persons (2–3 per cent of the population) representing less than 4 million small families and half-a-million "large" families — large in the sense of Indian "joint" families[4]. Probably, less than 10,000 persons every year (out of a total population of 680 million) enter the educationally privileged class from the under-privileged, changing the complexion of neither class.

For those who are educated, the day-to-day problems of survival are lessened. The survival of the uneducated, on the other hand, depends on their possessing abilities which would allow them to cope with the adverse environment in which they must live. Thus the uneducated of today would, as a result of evolutionary pressures, come to possess more "native" (that is inherited) intelligence, than the educated ones on whom by and large these pressures have not operated.

Since the intelligence tests cannot give a true indication of the native intelligence of a person who has been socially, culturally and economically deprived in early childhood, when the cultural patterns are often irrevocably fixed, the above-mentioned difference between the native intelligence of the long-deprived and the long-privileged would show up only when the two groups have had equal opportunities and a comparable environment to live in from the very beginning. A consequence of such a situation would be an apparent rise in the average intelligence of a population where there has been educational deprivation of a large population for a long period, as such deprivation disappears — as has happened in Japan since the 1930s.

If what I have said above is true, one could make two predictions: (1) what has been found in Japan should be found to be also true of other countries and populations where there has been democratization of education on a large scale in a relatively short time; and (2) the average IQ of those who have moved up from a traditionally educationally deprived state should be higher than of those who have been educationally privileged for generations due to circumstances of birth. We must, in that case also, conclude that in the United States, real democratization of educational and related opportunities has not occurred to the extent to which it has in Japan. The fact that the differences in IQ were found by Lynn even at the age of 6 could be merely an indication of the improved environment in Japan, in which the children were brought up to that age, as a consequence of the true educational status of the parents having improved across the population in the earlier generation(s).

Sequence software

SIR — In the article "Europe leads on sequences" (*Nature* 15 April, p.596), the problem of the collection of nucleic acid sequences is discussed. While it is a crucial problem, it is not the only one. Once collected, the sequences should be easily and quickly accessible to a large number of users, the mode of interrogation of the data base should be manifold, flexible and selective, and the answers should be immediate. Otherwise, the enormous effort required to set up a sequence library would be partly nullified by its limited use. At present, access to the data by most European users occurs by means of magnetic tapes, requested and sent by mail, containing all the sequences and related information stored in the library. The recipient of the tape then needs to read the entire tape on his own computer before the required information can be extracted. This procedure is time consuming and inefficient.

We have developed, on a computer Digital VAX/VMS 11-780 (Physics Institute, GNCB, Bari), an interactive software system for the retrieval and analysis of nucleic acid sequences. This system, which works in real time, offers a large number of options both for perusing and for analysing the data. No specific computer knowledge is required since the users, connected with remote terminals through telephone lines, are guided throughout their work. The main novel feature of the system is the mechanism of data retrieval, which is accomplished through the use of forty keys. Each key can be used alone or in combination with others. Among the available keys are: sequence code, bibliographic citations (journal, year of publication, personal communication), date of entry into the library, number of base pairs, function and biological source. Among eukaryotes, the selection can be made by kingdom, phylum or division, class, genus and species. An analogous selection is offered for prokaryotes. Viral nucleotide sequences can be retrieved by using the virus name, the genus, the family or the host. Biological groups of particular interest can also be selected, for example protozoa, bacteria, algae, fungi, lichens, higher plants, invertebrates and vertebrates. The outputs can be tailored to specific needs, through a choice of what to print and on which output device.

To test our software, we used sequences from a collection of about five hundred, kindly given to us by Dr Greg Hamm (European Molecular Biology Laboratory, Heidelberg) and by Dr Kurt Stüber (Genetics Institute, Cologne). These data were reorganized in order to make them compatible with our software. In planning the system, we took into consideration the fact that precise requirements and standards for a nucleic acid sequence library do not yet exist. Therefore, we incorporated into the software design provisions for great flexibility in terms of additions, deletions and changes.

This system is available to the scientific community upon request and without cost. We hope that it will become a useful research tool.

NEWS AND VIEWS

Atmospheric chemists *in flagrante*?

from Philip Campbell

OVER the past decade or so, the problems associated with the chemistry of the troposphere (the lowest 10 km of the atmosphere) have attracted increasing attention. The ecological effects of acidic rain and climatic effects of carbon dioxide have both generated many conferences and much media coverage. It was something of a change — even a relief — to see these topics recede (if only temporarily) within the general chemical perspective of a recent discussion meeting*. The organizers' declared aim was to assess the chemistry of the troposphere, particularly as influenced by biota and by the hydrosphere and lithosphere. Fundamental chemical questions were apparent. For instance, free hydroxyl radicals are now thought to be the most significant oxidizers in the troposphere, yet they can barely be detected using current techniques. With such problems being highlighted, the impression left by the meeting is that atmospheric chemists have been caught *in flagrante ignorantia* by their increasingly industrialized planet.

Apart from their chemical production in the atmosphere itself, tropospheric gases originate from volcanoes, oceans, man and his by-products and from biota and their detritus. Much attention at the meeting was focused on biogenic emissions, which represent virtually the sole source of such important trace constituents as ammonia and methane. Biological processes occur both on land and in the oceans of course, but the former, being arguably less homogeneous, present more problems.

A characteristic problem is: how representative are emission measurements of nitrous oxide from a particular site? That is, how reliably can they be extrapolated towards a global budget? Given the significant dependence of emission rates on crop and soil types, for example, and the influence of fertilizers, the need for comprehensive measurements is obvious — doubly so when temporal variations arise due to temperature dependence. More generally, given that compositions of many important trace species are in the parts per trillion (10^{-12}) by volume range, there were strong pleas for quality control of measurements and for accompanying background data on ambient UV and visible radiation for example. The latter are important because of the photodependence of important oxidation processes discussed below.

The source regions of the biosphere can be split into the oxic (containing free oxygen) and anoxic. The former include the upper layers of the ocean and of soils. As well as such fully oxidized species as carbon dioxide, oxic regions also produce such relatively reduced species as nitrous and nitric oxides from bacterial processes and ammonia from the decay of animal excreta. The anoxic environment (lower soil regions, and the interiors of animals for example) harbours the production of reduced species such as hydrogen sulphide (by sulphate-reducing bacteria) and methane (primarily by anaerobic bacteria in waterlogged soils and in termites).

As well as the specific uncertainties associated with such emission processes, participants highlighted the problems of modulation and transport in the biosphere. This problem is well illustrated by hydrogen sulphide. Bacterial reduction of continental shelf sediments is thought to result in a billion (10^9) tons of H_2S being produced every year, yet only a few million tons reach the atmosphere. The balance is taken up by oxidation in the upper layers of the oceans or, more to the point, by biological oxidation by sulphur bacteria which, in this manner, consume the gas with extreme efficiency. Similar processes have been observed with nitrous oxide.

As layers of bacteria only fractions of a millimetre thick can have a significant role, participants emphasized the care required when measuring fluxes between environmental 'compartments'. In contrast, rarer volatiles such as carbonyl sulphide and dimethyl sulphide (DMS) slip through the bacterial net. DMS is a very important carrier in the global sulphur cycle, being produced by marine algae and having a strong ocean–atmosphere flux. Investigation into possible continental sources of this and other volatile sulphur compounds was placed high on the conference shopping list.

It is now clear that the tropospheric chemical fates of virtually all the important trace gases are governed by free hydroxyl radicals. As R. J. Cicerone (National Center for Atmospheric Research, Boulder) remarked, this statement would have been ridiculed a decade or so ago when few believed that electrically neutral free radicals could exist in the troposphere. In 1971, however, H. Levy suggested that excited oxygen atoms produced by the well known UV photolysis of tropospheric ozone would react with water to produce free hydroxyl radicals. These highly reactive species, present in minute (and at present barely detectable) quantities, oxidize important trace species such as methane, carbon monoxide, hydrogen sulphide, ammonia and a host of others.

It is obviously important, therefore, that the temporal and spatial behaviour of tropospheric ozone be well understood. An important source is downward diffusion from the stratosphere. However, hydroxyl radicals also play an important part in determining tropospheric ozone concentrations, because they fill the role of active catalysts both in its production (permitting the oxidation of carbon monoxide by oxygen) and its destruction (where ozone oxidizes carbon monoxide to produce carbon dioxide and oxygen). These processes require reaction sequences which involve NO and NO_2 and produce the intermediate species HO_2. Thus, it was strongly recommended that the atmospheric distributions of these species and of O_3 and OH be intensively investigated. Such work will require the further development of experimental techniques due to the minute quantities of some of the species concerned. Also essential will be the continuation of laboratory kinetic studies since a knowledge of rate constants is central to atmospheric chemical modelling.

The hydroxyl radicals are one example of the significant role of gas-phase catalysis, where minute quantities of a trace species will significantly affect not only the chemical but also the thermal balance of the atmosphere. Thus, those currently concerned about the effects of chloro-

*The Dahlem Workshop on Atmospheric Chemistry was held in Berlin on 2-7 May 1982.

Philip Campbell is Physical Sciences Editor of Nature.

0028-0836/82/260009-02$01.00

fluorocarbons on stratospheric ozone (another example of such catalysis) may broaden their attention downwards as the very complex tropospheric pathways become better understood.

Although the oxidation processes described above are important, others may be equally so and are equally ill defined at present. An important example is that of SO_2. The concentrations of SO_2 and C_2H_2 observed in the remote troposphere are roughly the same although their emissions from combustion are in the ratio of 100:1. Their gas-phase oxidation rates by hydroxyl radicals are similar, so some other mechanisms for SO_2 removal exist. One of these is wet-phase oxidation.

It was remarked that atmospheric aqueous chemists appear to be at the stage reached by their gas-phase colleagues a decade or so ago, with islands of information in a sea of uncertainty. Although the chemical components in atmospheric water are moderately well known, their reactions are still very uncertain. The main oxidizing agents are thought to be H_2O_2, O_3 and O_2, and the best (or least poorly) understood process probably the aqueous oxidation of SO_2 to sulphate, of obvious relevance to acidic rain. Aqueous kinetics are strongly pH dependent and depend also on the presence of catalysts such as manganese ions and graphite. There are unpublished observations that indicate that H_2O_2 may be much more prevalent in rainwater than previously thought. Complications include photochemical effects and the fact that equilibrium may not be reached in raindrops.

The probable importance of transition metals for aqueous catalysis was emphasized together with the uncertainties concerning their chemical form. For instance, organic complexes of transition metals have been observed to drastically enhance oxidation of reduced sulphur compounds, while complexation of reduced iron and manganese inhibits their catalytic abilities. The need for laboratory studies of such problems is urgent, together with field identification of complexes in rainwater, aerosols, and so on.

Other uncertainties in the aqueous phase are associated with gas solubilities. G. Ayers (CSIRO, Mordialloc) reported measurements of ammonia in rainfall that indicated considerably lower solubilities than expected. Whether the difficulties lie with the earlier measurements of the Henry's Law constant or with unknown processes peculiar to rainwater is not known. Given ammonia's importance in providing atmospheric alkalinity, such problems (which may also become apparent for other trace species) would appear to be fundamental.

Although the topic of the conference was chemical, the problems of aqueous chemistry are closely linked with the physics of the water cycle itself (for instance, repeated condensation and evaporation within clouds). Moreover, the means by which atmospheric constituents are incorporated into raindrops, snow and aerosols require detailed investigation, because they not only affect the chemical transformation of species but also represent an important atmospheric sink in global budgets. As an example, and in a memorable display of technical bravura, W.G.N. Slinn (Battelle-Pacific NW Labs, Richland) demonstrated the cleansing action of rain through its depletion of in-flight insect populations.

Given the wide range of outstanding but clearly identified problems associated with the chemistry of today's atmosphere, it would seem presumptuous to consider tackling the equivalent problems of the past, where only a few species have so far been directly identified (as opposed to inferred). Nevertheless, one group of participants was allotted the task of assessing the records of past atmospheric composition. Ice cores, lake and marine sediments and tree-rings can together provide information over the Quaternary period (the past two million years or so), the tree-ring interpretations being dependent on models of leaf uptake and transfer and so on. Ice-cores from Greenland and Antarctica offer the most direct record of composition, stretching back 10^5 years or more, but practitioners are the first to acknowledge that considerable work is required before the full potential of this resource is realized. Further back in time, the geological record requires a considerable degree of inference to yield compositional information. Past carbon dioxide concentrations are of obvious importance to the climatologists owing to their attendant greenhouse tendencies, and climatic change is more directly documented in sediments than composition.

This has necessarily been a selective review of a wide-ranging meeting, concentrating, for instance, on the inorganic gaseous constituents of the troposphere. But considerable attention was also given to the sources and fates of organic species (for which data are scarce) and of metalloid compounds [such as $(CH_3)_4Sn$]. Another extremely important set of atmospheric constituents is the aerosols, whose impact on the chemical balance of the troposphere is profound, and whose composition, physical characteristics and chemical and physical evolution (nucleation and transport) need extensive investigation. □

A corona around the Milky Way

from Joel N. Bregman

MANY new observations in the UV, X-ray and radio wavelength regions indicate that a multi-component corona of hot and cool gas surrounds the disk of our Galaxy. Unlike the disk itself, which is rich in relatively easily studied neutral and ionized gas and cosmic rays, the components of the surrounding region have proved difficult to investigate. Attempts are now being made to fit the new observations to coronal models in which the activity of the disk gives rise to the corona and the heating and cooling processes naturally cause phase changes in the gas, resulting in a complex corona.

Evidence that clouds of gas exist above the disk first came from observations of the Ca II absorption lines against the optical continua of stars, by Münch and Zirin[1]. The optical absorption lines are produced by cool ($<10^{3.5}$K) clouds of gas but Münch and Zirin[1], in studies of stars far above the disk, discovered more absorption lines than could be accounted for by gas clouds in the disk alone. Several recent studies, in which UV spectra of hot, distant stars were obtained with the International Ultraviolet Explorer (IUE), support and greatly extend the earlier optical work. Absorption lines of Si IV and C IV, commonly seen in these UV spectra, originate in either collisionally ionized gas at 10^5K or photoionized gas at 10^4K. It is not yet possible to measure directly the distance to individual clouds, but distances can be calculated by interpreting the absorption line velocities with a model for galactic rotation. The clouds probably lie within 30,000 light yr of the galactic disk[2–4] (while, for comparison, the half-thickness of the disk is only 600 light yr).

X-ray observations reveal that another component of the corona is gas considerably hotter than that responsible for optical or UV absorption lines. The Wisconsin X-ray group find an X-ray background flux (1 keV), some of which is associated with the Galaxy and probably originates above the disk in a flattened corona[5]. Unfortunately, they are unable to distinguish between emission from point sources (stars) and diffuse gas, nor do they directly measure the distance to their emitters. Nevertheless, these observations at least are consistent with a hot diffuse corona ($\sim 3\times10^6$K, $n\sim10^{-3}$ cm^{-3} if the height of the corona is that suggested from optical studies).

Radio observations complete our current understanding of the corona. Observations of the 21 cm hyperfine transition of neutral hydrogen show many

0028-0836/82/260010-02$01.00

cool clouds ($< 10^3$K) with high velocities[6]. Because these velocities cannot arise from galactic rotation of ordinary disk gas, several investigators have suggested that the clouds reside in the corona and may be falling towards the disk[7-10]. Radio measurements of pulsars show that the pulsed radiation is dispersed by electrons of mean density $0.025\ \text{cm}^{-3}$ and scale height greater than 1,500 light yr (ref. 11). Finally, a weak low-frequency radio continuum background[12] that is probably synchrotron emission from cosmic rays interacting with the coronal magnetic field is observed. These observations are consistent with the model if there are significant cosmic ray intensities at distances greater than 3,000 light yr from the disk[13]. The galactic disk thus seems surrounded by a thick corona composed of thermal gas at several temperatures ($< 10^4$K, 10^4–10^5K, $\geq 10^6$K) as well as cosmic rays and magnetic fields.

Although no single theory explains the presence of all these components, progress has been made in linking some of the components together. Spitzer[14] pointed out that if million degree gas could escape the disk, it would surround the Galaxy with a corona several tens of thousands of light years thick. This corona would lose thermal energy through radiation in a process such that cooling condensations of gas would grow quickly and form into clouds much cooler ($\leq 10^4$K) than the rest of the corona[7-10]. These clouds may fall into the disk, merge with the interstellar disk gas and eventually re-emerge as hot gas again, in a cycle that has been termed a 'galactic fountain'. For certain temperatures and densities of the hot coronal gas, the theoretical velocity pattern of the cool clouds roughly reproduces that of the high-velocity clouds of neutral hydrogen[9]. While the interior of these cool clouds is probably neutral, their surface may be photoionized by soft X rays, or by photons from hot stars. The ionized surface layer would be the site of the Si IV and C IV absorption lines seen in the UV spectra. Although this model links together the various phases of the thermal gas, it is not without problems, one being that cosmic rays are not included.

As a first step towards remedying this omission Hall[15] has considered the connection between a hot turbulent corona, and the propagation of cosmic rays and the structure of the magnetic field. In this model, the cosmic rays occupy approximately the same volume as the hot corona and large-scale turbulence in the hot gas causes magneto-hydrodynamic instabilities which result in small-scale density fluctuations and magnetic field irregularities in the gas. Consequently, cosmic rays are scattered as they propagate through the corona in such a way that the size of the cosmic ray corona and the diffusion coefficient within it can be accounted for. □

Sons and daughters

from T.H. Clutton-Brock

In some species of invertebrates, the sex ratios of emerging adults can vary from nearly 100 per cent males to nearly 100 per cent females[1,2]. Although the immediate causes of sex ratio variation are diverse — in some species, sex ratios are controlled by environmental conditions during growth while in haplo-diploid organisms they depend on the proportion of fertilized to unfertilized eggs laid — the evidence that they represent adaptive strategies of reproduction is overwhelming[2]. But can diploid organisms such as birds and mammals, where sex is chromosomally determined, vary the sex ratio of their progeny in an adaptive fashion, too? The traditional view is that they can't[3] but several recent studies have challenged this position.

The most sensational of these claims, made by Nancy Burley of the University of Illinois, is that coloured leg rings fitted to the legs of zebra finches not only affected their attractiveness as mates but also influence the sex ratio of the progeny they produce[4]. According to Burley, pairs generally bias the sex ratio of their offspring towards the sex of the more attractive parent; for example, those in which the male wears an 'attractive' ring and the female an 'unattractive' one tend to produce male-biased sex ratios. This arrangement, Burley argues, will increase parental fitness.

Not surprisingly, the publication of these claims evoked a strong response. Many laboratory and field studies of social behaviour in birds use colour rings. How many effects might have been obscured — or produced — by the colour of the rings used? How many population explosions — or crashes — could coloured leg rings have caused? Two critiques of Burley's paper have been recently published in *Science*[5,6] and although Burley rebuts some of the criticisms in the same issue, the small size of her sample and the absence of any relationship between the reproductive success of males and the sex ratio of their offspring in other bird species[7,8] indicate a strong need for her experiments to be replicated before their generality is accepted.

What of other cases of variation in secondary (birth or hatching) sex ratios in birds and mammals? In many cases, suggested effects do not approach statistical significance[9-11]. In addition, a proportion of significant trends are likely to be fortuitous: sex ratios have universal interest and it is probable that few biologists with access to breeding data fail to look for consistent trends, publishing only if significant effects are found. Since there is no way of estimating the number of those looking for variation in sex ratios, it is impossible to tell what proportion of significant trends could have arisen by chance. There are certainly many data sets in which no sex ratio bias is evident[8,11-13]; in particular, the search for genetic variance in the sex ratio among outcrossed vertebrates has been largely unsuccessful[14]. Where genetic effects have been implicated, they are typically very small indeed; for example, an analysis of 150,000 births sired by 107 bulls found significant differences in the sex ratio of progeny sired by different fathers but, after correcting for the expected binomial variation, the standard deviation of the proportion of males produced was only 1.5 per cent[15].

Nevertheless, a growing number of studies suggest that secondary sex ratios can and do vary among birds and mammals. Birth sex ratios not uncommonly differ from unity in mammals: female-biased ratios are uncommon while a considerable number of sexually dimorphic mammals, including man, show male-biased birth sex ratios which differ significantly from unity in large samples[16,17]. Exceptions include two species of lemmings which produce around twice as many daughters as sons, apparently because a proportion of females are of XY karotype with an X chromosome that causes its bearer to be a female and to produce mainly or exclusively X-bearing eggs[18-20].

Secondary sex ratios also vary within species. In laboratory mice maintained on low-fat diets, birth sex ratios fell from 50 per cent male in a control group to 24 per cent among experimental animals[21], while a group of female white-tailed deer maintained on a low plane of nutrition produced 70 per cent sons compared with

Table 1 Relationship between fawn sex ratio and the temporal interval between onset of oestrus and insemination in white-tailed deer (from ref. 25)

	Hours in oestrus					
	13–24	25–36	37–48	49–96	Total	$\bar{x}$
Male fawns	4	12	25	21	62	
Female fawns	24	19	15	5	63	
Per cent males	14.3	38.7	62.5	80.8		49.6
No. of does	15	15	21	16	67	
Fawns/ mother	1.87	2.07	1.90	1.69		1.88

47 per cent among females reared on a high plane of nutrition[22]. Significant associations between birth sex ratios and the timing of insemination relative to ovulation[23,24] have been demonstrated in several studies of human data and in a recent experiment with white-tailed deer (see Table 1). More males are born early in the breeding season in some seals[26-29] as well as in red-winged blackbirds[8] while this trend is reversed in some other birds[30]. Two recent studies of baboons and macaques show that socially dominant females produce more daughters than sons while subordinates produce more sons than daughters (Table 2). And in several ungulate species there is evidence that more males are produced at high population density[33] while research on rodents indicates that birth sex ratios vary significantly with the population cycle[34,35]. In none of these cases is the mechanism responsible for the variation in sex ratio yet known but the effects should not be lightly dismissed on this score. Both male- and female-biased mortality can occur during gestation[36-43] and the possibility of variation in the sex ratio at conception cannot be excluded (see refs 44–46).

A central question is whether variation in secondary sex ratios is adaptive — as is clearly the case in haplo-diploid organisms.

Table 2 Sex ratios in relation to maternal dominance rank in macaques and baboons

Species	Maternal rank		
Papio cynocephalus	High		Low
(Wild population: ref.31)			
Females	19		7
Males	10		15
Per cent males	29		22
Macaca mulatta			
(Captive group: ref. 32, Simpson, unpublished)			
1972–1981	High	Medium	Low
Females	20	12	13
Males	9	19	20
Per cent males	31	61	61
Pre-1972	High		Others
Females	18		7
Males	6		15
Per cent males	25		68

Trivers and Willard[47] argued that in species where reproductive success varies more widely among males than females and parental investment influences the success of offspring, females should produce more sons at times when they are in superior body condition (and so can afford to invest heavily in each offspring) and more daughters when in inferior condition, perhaps adjusting the sex ratio of their progeny through sex-differential mortality among their offspring. Their theory was subsequently disputed[10] but has since been shown to be robust[8,48], though the evidence cited in support of it is unconvincing[10].

Some cases appear to agree with the predictions of Trivers and Willard's theory. The low proportion of males produced by mice reared on poor diets[21] fits Trivers and Willard's predictions and so, too, may the female-biased sex ratios produced by early breeding grackles[30]. Other studies have shown that under circumstances of food shortage male neonates are less likely to survive[49,50], though an alternative explanation is that increased mortality is one of the costs of faster growth rates, higher metabolic rates and reduced fat deposition among growing males in dimorphic species[51].

However, there are as many trends that apparently contradict the predictions of Trivers and Willard's theory, including the tendency for female white-tailed deer maintained on a low plane of nutrition to produce male-biased sex ratios[22] and for dominant baboons and macaques to produce female-biased ones[31,32]. These results could still be fitted within the framework of the theory if breeding success proved to vary more widely in females than males. Alternatively, parental investment may sometimes have a greater *effect* on females than males — for it is the effects of parental investment on variance in the reproductive success among male and female offspring rather than the amount of variance *per se* that will determine which sex a parent should invest in most. A difference of this kind has been invoked by Altmann[31] to account for the female-biased sex ratios produced by dominant baboons: in this species, as well as in rhesus macaques, the reproductive success of females is related to the rank of the matriline to which they belong and dominant mothers may be able to influence the reproductive success of their daughters more than that of their sons. But it is important to remember that neither variation in lifetime reproductive success nor the effects of parental investment on success have yet been measured in both sexes in any wild vertebrate.

Other functional relationships may also be involved. The tendency for late inseminations to produce male-biased progeny could allow individuals to bias the sex ratio of their offspring towards the rarer sex[35] — an effect which has been experimentally demonstrated in guppies[52]. In species where females remain in their natal area while males disperse, sisters may compete with each other for food and male-biased sex ratios may be favoured[53], especially when population density is high. Conversely, where populations are divided into small inbreeding populations, competition between brothers for mates may favour female-biased ratios — which could explain the occurrence of female biases among lemmings[54]. Where males are more likely to die before the termination of parental investment, an excess of males may be produced at birth[16,55] — an argument originally produced by R. A.

Fisher to explain the existence of male-biased birth sex ratios in man[16].

Alternatively, sex ratio variation may sometimes be a non-adaptive consequence of an adaptive mechanism. For example, in baboons and macaques, females are likely to remain in the troop where they are born throughout their lives and mothers may be able to increase the reproductive success of their offspring by removing as many potential competitors as possible[56]. In several species, there is evidence that female juveniles are more likely to be attacked or threatened by conspecifics than males[57,58], and one study has even suggested that this effect may extend to females pregnant with female fetuses[40], possibly increasing the likelihood that subordinates will abort if they have conceived daughters.

However, the basis for adaptive explanations of sex ratio variation in vertebrates is weak because we know virtually nothing about the extent to which parental investment affects the reproductive success of sons and daughters in wild populations or the environmental factors that modify its influence. In addition, the very flexibility of adaptive arguments undermines their credibility since there are few trends to which a plausible, adaptive explanation could not be fitted. Before accepting such arguments, we need to know considerably more about the distributions of the effects they claim to explain. How is maternal rank related to the sex ratio in primates where daughters do not inherit their mother's rank? Is high population density associated with female-biased birth sex ratios in species where daughters disperse and sons remain in their natal area? Do species which show particularly biased birth sex ratios also show especially strong sex differential mortality during early growth? And how is sex ratio variation achieved? Until these questions have been examined, we shall continue to be left with some interesting data, a plethora of stimulating ideas and few firm conclusions.

Decapentaplegic — hopes held out

from Gary Struhl

FRUIT flies are composed of around a million cells arranged in a miraculously complex pattern. Each eye, for example, contains about 700 facets arranged in a crystalline lattice; each facet is itself a precise hexagonal array of specialized receptor, pigment and accessory cells. How such intricate patterns arise is a central problem in developmental biology. In the case of the eye, it was once thought that each facet arose independently as the descendent of a single cell. But this simple lineage model fell by the wayside with the discoveries that facets are not clones[1], and that any two cells in a cluster of neighbouring facets can arise as daughters from the same mother cell[2]. Thus, in the eye, as in most other tissues of the adult epidermis, cell patterns are not dictated by cell ancestry, but rather by interactions between cells. And in order for such interactions to give rise to the coherent cell patterns of organs and appendages, there must be mechanisms for organizing and interpreting spatial information in large populations of cells.

At present, we can only speculate about how cells know where they are in a developing tissue, and how they use this information to decide what to do. Whatever the mechanism, however, its components must be molecules encoded by genes, and this fact provides one of the few approaches to understanding how cell patterning occurs. In principle, it should be possible to identify the particular genes whose products are responsible for organizing and interpreting spatial information, and, once identified, it should be possible to isolate such genes, purify their products and determine their mode of action at the molecular level.

Unfortunately, there is at least one serious flaw in this golden scenario — how does one identify the relevant genes? There are of the order of 10^4 genes in the *Drosophila* genome, of which only a few are probably integral components of the cell patterning mechanism. At present, the only criterion for finding these few needles buried in the genomic haystack is mutant phenotype. But here is a catch-22: without a clear understanding of the mechanism in question, it is difficult to predict the phenotypes of mutations which eliminate its component parts. So choosing the right genes is a difficult business, depending as much on chance and intuition as on objective arguments. And unfortunately, an error in judgement may go undetected for several years.

In a recent paper[3], Spencer *et al.* have described a complex genetic locus in *Drosophila*, *decapentaplegic* (*dpp*; otherwise called *held out*[4]), which they suggest encodes a series of related gene products involved in positional signalling. If their suggestion is correct, understanding how the products of this locus work will be of fundamental importance. What is their evidence? Briefly, they have obtained a series of mutations in this locus which result in the absence of specific parts of the adult appendages. The mutations fall into several discrete classes which can be arranged in an order such that low-class mutations remove only a few distal structures in each appendage, whereas progressively higher-class mutations remove more and more proximal structures (the highest-class mutations appear to kill the embryo). In addition, the functional genetic units defined by the different classes of mutation are arranged on the chromosome in an order that corresponds directly with their phenotypic hierarchy. On the basis of these results, the authors "presume that the functional units in the *decapentaplegic* complex correspond to a series of structural genes encoding activities in morphogenetic positional signalling".

Because this work may comprise the foundation of a detailed genetic and molecular analysis, it is well to ask how good this presumption is. At its basis lies the assumption that loss of distal structures results from absence of positional signalling along the proximo-distal axis. As Spencer *et al.* note, there is no easy way to assess the validity of this assumption. Consequently, one must bear in mind that there may be other less interesting explanations for the preferential loss of distal portions of adult appendages. For example, distal portions of most imaginal disks may proliferate more rapidly than proximal portions; it is possible that in the absence of the *decapentaplegic* gene(s), rapidly proliferating cells may accumulate a toxic metabolite, or run out of an essential metabolite, thereby leading to cell death and consequent loss of structures.

It may help to compare the phenotypes of *decapentaplegic* mutations with the phenotypes of other mutations thought to be primary defects in the cell patterning mechanism. For example, homeotic mutations, exemplified by mutations of the *bithorax* complex[5], result in particular parts of the animal developing like other parts (for example, some of the abdominal segments developing like the second thoracic segment). That is, they result in the replacement of one cell pattern by another. In addition, such mutations transform the cell pattern of both the larval and

adult epidermis in a corresponding fashion. A second example is that of mutations such as *engrailed*[6] and the segmentation mutations isolated and described by Nusslein-Volhard and Wieschaus[7] which alter the pattern of all segments in a homologous fashion. These mutations affect all segments of the embryo, and in a few cases all segments of the adult. Moreover, they generally result in deletion of a particular portion of the segment and in mirror image duplication of the remaining portion. Again, as in the case of homeotic mutations, these mutations result in phenotypes which may be described as the replacement of one cell pattern by another. Also, like the homeotic mutations, they alter the cell pattern of the embryo, and hence affect cells which have not undergone extensive proliferation.

Whether mutations which result in the replacement of one cell pattern by another are more likely to be relevant to the process of positional signalling than mutations which simply eliminate homologous portions of cell pattern is anybody's guess. Similarly, it is difficult to assess whether mutations which alter cell pattern in precise ways in the absence of extensive proliferation are of more interest than mutations which cause the elimination of proliferating cells. In the case of the *decapentaplegic* complex, further descriptions of mutant phenotypes at the cellular level may help to bolster the argument that this gene complex plays a specific part in positional information. But ultimately, the validity of this argument, or lack thereof, may only be apparent after all the hard work is done — when we understand the molecular roles of the *decapentaplegic* gene products. □

Synthetic peptides as the basis for future vaccines

from John Beale

MOST antigenic determinants of proteins are thought to be conformational rather than sequential; they depend upon the three-dimensional folding of the molecule rather than on the linear sequence of amino acids. Jim Bittle and his colleagues provide in this issue of *Nature*, p.30, an example of the importance of the primary amino acid sequence for foot-and-mouth disease virus (FMDV). They synthesized peptides corresponding to several regions of the virus polypeptide VP1 and found that one of them, corresponding to amino acids 141–160, when coupled to keyhole limpet haemocyanin (KLH) and given with an adjuvant, produced neutralizing antibodies to FMDV and protection against challenge in animals. Another peptide, containing amino acids 201–213 of VP1, also produced neutralizing antibodies. This is an exciting result for both theoretical and practical reasons.

The fact that alteration of conformation by denaturation or enzymatic digestion greatly changes antigenicity suggests that most antigenic determinants of proteins are conformational rather than sequential. For foot-and-mouth disease, for example, the viral peptides derived from either infected cells or disrupted virus have lost most of their immunogenicity; genetically engineered VP1 is also of low immunogenicity[1]. However, several recent lines of evidence suggest that small synthetic peptides having the sequence of antigenic determinants on a protein will, in fact, react with antibody to the intact native antigen and in some instances will neutralize its biological activity.

Langbeheim, Arnon and Sela[2], for example, found that a 20 amino acid peptide corresponding to amino acids 89–108 of the coat protein of MS2 phage, when coupled to a carrier, induced antibodies in animals which neutralized the phage and were as effective as antibody to the intact phage or the coat protein. The neutralization test involved the use of goat antiglobulin which may have produced neutralization without the primary antibody binding to a specific neutralizing site. Peptides representing other regions of the coat protein were ineffective. Similar results come from synthetic peptides corresponding to the antigenic determinant regions of diptheria toxin[3] and the natural cyanogen bromide immunizing fragment of the M protein of type 24 *Streptococcus pyogenes*[4]. Success with hepatitis B virus has also been achieved by several groups, although protection in chimpanzees has not yet been reported (see A. Zuckerman *News & Views* **295**, 98; 1982). Attempts to reproduce the native conformation of the antigenic determinant by producing a cyclic peptide[5] did not yield an antigen clearly superior to the linear peptides[6].

The situation with influenza virus is more confused. Studies of variants using monoclonal antibodies and X-ray crystallography[7] have provided very precise information about the amino acid sequences and the antigenic sites, so the effectiveness of synthetic peptides would be confidently predicted. In the event, although antibodies raised against several KLH-linked synthetic peptides could react with influenza haemagglutinin, they did not react with the previously delineated antigenic sites[8]. Moreover, antibodies raised against the haemagglutinin did not react with the synthetic peptides. These results suggest conformation of the molecule is important.

A key question is whether synthetic peptides can form the basis for a practical vaccine. The results so far obtained have great promise. Peptides with differing specificities might even be coupled to a single carrier protein to give a multivalent vaccine. Problems still remain to be solved, however, some applicable to all vaccine candidates and others more specific to particular vaccines. For foot-and-mouth disease, a synthetic vaccine would have to compete with existing vaccines which are produced by highly developed technology and are very efficient and cheap. Nonetheless, existing vaccines have some problems. First, safety: a number of outbreaks of foot-and-mouth disease have been associated with failures of the inactivation process. The most recent outbreaks in Jersey, and on the Isle of Wight, almost certainly derived from such an accident, as was shown by careful analysis of the molecular characteristics of the virus which showed striking identity between vaccine strains and strains isolated from outbreaks (ref.9 and see J. Brooksby *News & Views* **293**, 431; 1981). Clearly, a synthetic peptide overcomes these problems, but in truth, safety is not a problem if formalin is avoided as an inactivating agent. This chemical has well established limitations for viral inactivation but when acetyl ethyleneimine is substituted there are no problems with inactivation of FMDV. A second consideration is effectiveness. There are several problems for existing vaccines; first, antigenic variability. One of the reasons for suspecting that the two regions on VP1 would be effective immunogens was that they vary in amino acid sequence from strain to strain. New synthetic peptides will be required for each strain but the process of cloning and sequencing the VP1 in order to identify new peptides to synthesize should be simple. Indeed, a number of new peptides might be made ahead of time. Some strains grow poorly in cell culture and are poor vaccine strains for this reason, whilst others are very unstable or are poor strains for less clearly defined reasons. These problems may well be solved by the use of synthetic peptides. Similarly, all foot-and-mouth disease virions are relatively unstable, especially at below *p*H 5.0 and at ambient temperatures; again synthetic peptides are likely to be superior because they are more stable. The existing vaccines are effective after a single dose when given with an adjuvant, usually absorption to aluminium hydroxide and saponin for cattle and an oily adjuvant for pigs. So far, the vaccines prepared from VP1 produced

John Beale is at The Wellcome Research Laboratories, Langley Court, Beckenham, Kent BR3 3BS.

0028-0836/82/260014-02$01.00

in *Escherichia coli* have proved less effective than existing vaccines. Thus, even after two doses, antibody levels are much lower than after a single dose of conventional whole-virus vaccines. Synthetic peptides are reported by Bittle *et al.* to be far more effective than VP1 but this comparison is a bit unreal for two reasons: first, the VP1 they used was prepared by SDS treatment and polyacrylamide gel electrophoresis which is a denaturing step and may hide the sites in VP1 reacting with anti-peptide sera or with native virions. Also, VP1 is a relatively small protein, whereas the synthetic peptide was coupled to KLH, one of the most immunogenic carrier proteins in the immunologist's repertoire. The results of coupling VP1 produced by genetic engineering to a similar immunogenic carrier would have been a more valid comparison. Perhaps the most encouraging feature, however, was the almost equally good results they obtained from a single dose using aluminium hydroxide compared with Freunds adjuvant. The dose schedule and duration of immunity are important aspects of vaccine development. As noted earlier for foot-and-mouth disease vaccine, because of the difficulty of mustering animals for vaccination, protection is required from a single dose, but two to three doses may be given each year. For many other vaccines a two-dose primary schedule can be followed by booster doses over a period of years. The performance of vaccines based on synthetic peptides in these respects will need study, but there is no reason to suppose they will prove less efficient than existing killed vaccines.

The feasibility and economics of synthetic peptide vaccines are difficult to judge. The situation for foot-and-mouth disease, where there is an existing relatively cheap vaccine, is very different from that of hepatitis B, for example, where the vaccine is very expensive and can be made only on a limited scale. Another key factor will be the degree of purity of the peptides required. Lerner and his colleagues did not make any special efforts to purify the peptides that are produced by the Merriefield solid-phase synthesis. Plainly it will be essential to establish that the effects are due to a peptide truly of the sequence deduced from DNA sequencing. The degree of purity ultimately required will doubtless vary according to the application. It will be necessary to have a synthetic process that consistently produces the same product — no doubt the spur of a practical application will lead to improved methods and reduced costs. The size of the peptide to be made will be a key factor. Another important element requiring more research is the carrier. In the present experiments with FMDV, KLH was used but it seems certain to be superseded because of supply problems. The addition of a carrier such as KLH negates some of the advantages of a defined synthetic vaccine and problems of hypersensitivity to the carrier may occur when repeated injections are necessary. Clearly there are alternative carriers, such as tetanus toxoid or poly-DL-lysine, and this is an important matter for more research.

Similarly, there will be a need for an adjuvant. Aluminium hydroxide is a clinically acceptable adjuvant for man and it is encouraging that it worked for FMDV. The question of the adjuvant is linked to the requirement for a carrier and the best combination will need to be reassessed. Knowledge about adjuvants is at present a dark area of immunology.

The work of Bittle *et al.* is a significant step along the road to synthetic vaccines. It opens up exciting possibilities for vaccine development which should be vigorously pursued. □

The internal evolution of Venus and the galilean satellites

from Sean C. Solomon

THE solid planets and satellites of this Solar System display a great diversity of surface features. The Moon and Mercury and many of the icy satellites of Jupiter and Saturn have heavily cratered terrains that have been little altered for billions of years. Jupiter's moon Io has been continuously resurfaced over periods of millions of years by vigorous volcanic eruptions fuelled by the dissipation of huge solid-body tides. The Earth has a lithosphere underlying the ocean basins that is recycled by plate tectonics over a period of about 100 million years. Despite their differences, all these bodies have been shaped by common physical processes during their formation and subsequent evolution. A continuing challenge, made evident by the many new results on the internal and surface evolution of planets and satellites presented at the 13th Lunar and Planetary Science Conference*, is to understand how these common processes have produced the observed diversity of Solar System objects.

Particular interest at the conference was focused on Venus and the galilean satellites of Jupiter, all objects of recent scrutiny by US and Soviet spacecraft.

Dramatic new results have come from Venera 13 and 14 which landed on Venus on 1 and 15 March respectively (V.L. Barsukov and Yu. A. Surkov, Vernadsky Institute of Geochemistry and Analytical Chemistry; and see *News and Views* **296**, 607; 1982). Most notable are the chemical analyses of compositions of Venus soils, derived by X-ray fluorescence, that indicate similarities to a high-potassium alkali basalt at Venera 13 and a terrestrial oceanic tholeiite at Venera 14. On Earth tholeiites, because they comprise the upper igneous crust of all ocean basins, are the most common volcanic rock type. Discovery of such basalts on Venus supports the hypothesis that the major-element compositions of the two planets and their respective mechanisms for the formation and eruption of basaltic magma are similar.

Detailed comparisons of Venus and Earth with respect to planetary composition, mechanical properties and tectonic evolution were also presented. The bulk density of Venus, after correcting for the effects of compression, is generally estimated to be about one per cent less than that of the Earth[1]. The difference is often explained in terms of a slightly different composition for the two planets[1,2]. K.A. Goettel (Washington University) suggested that Venus may have a bulk density at standard conditions equal to or greater than that of the Earth. Such a result would hold if internal temperatures are significantly higher for Venus than for Earth at comparable depths and if Venus has a thicker layer of basaltic crust[3]. The required higher temperatures may occur, however, only if Venus has no analogue to terrestrial plate recycling[4]. If Goettel's suggestion is correct, then cosmochemical models for inner planet formation will require revision.

There is much debate over whether some version of plate tectonics operates on Venus. The issue has broad implications for our understanding of heat transfer and surface evolution on silicate planets. H. Spetzler, I.C. Getting (CIRES, University of Colorado) and H. Mizutani (University of Nagoya) have made a new contribution in a theoretical formulation for brittle failure in silicate planets based on stress corrosion theory and the interaction of growing cracks. Including the effects of

water on the rate of crack growth, they have calculated the effective failure strength as a function of depth in each of the terrestrial planets. For Venus, assuming the partial pressure of H_2O in near-surface rocks to equal that in the lower atmosphere, they calculate a very low value of crustal strength (about 10 MPa) and conclude that plate subduction on Venus would be unlikely.

This author and J.W. Head (Brown University) took a different view. Venus must lose an amount of heat per mass roughly comparable to that known for the Earth[5]. Solid planets and satellites transfer internally generated heat to the surface by plate recycling, as on Earth[6], lithospheric conduction, as on the Moon, and hotspot volcanism, as on Io. Each has been suggested as the dominant mechanism for lithospheric heat transfer on Venus[6–8] and we argued that none can be ruled out given our present knowledge of the venusian surface. In particular, plate recycling cannot be excluded once it is recognized that the characteristics of plate divergence and convergence zones on Venus and Earth will be different because of the different surface temperatures (740K on Venus) and surface abundances of water. Whatever the dominant mechanism of lithospheric heat transfer, however, given a global heat loss per mass comparable to that for the Earth, we must conclude that most of the large-scale topographical features on Venus are young compared with the surface ages of the smaller terrestrial planets.

The galilean satellites, because their surfaces are cold and are composed of unusual materials, display landforms and surface histories that are difficult to understand simply by extrapolation from the known outcomes of processes on the terrestrial planets. Europa, for instance, has a high-albedo icy surface criss-crossed by numerous darker lineations of great length and probably of tectonic origin[9]. T.B. McCord (University of Hawaii) and colleagues reported on a new spectral unit map of Europa derived from Voyager multispectral images. At least four distinguishable units occur; the darker lineations are spectrally similar to other dark units. E. Schonfeld (Johnson Space Center) proposed that the brown colour of the lineations and the low reflectance of the satellite at 3–4 μm may be due to the presence of organic molecules erupted from Europa's interior during episodes of aqueous volcanism. Interpreting the lineations as lithospheric fractures, P. Helfenstein (Brown University) showed that they may be the result of tidal stresses, although the details of such an explanation are considerably more complicated than in earlier versions[10].

The galilean satellites Ganymede and Callisto are similar in size and bulk density, yet their surfaces differ markedly[9]. Callisto displays a surface that has been little altered since an era of heavy impact bombardment. Ganymede, however, preserves heavily cratered units but also contains younger and more lightly grooved terrain, thought to be of extensional tectonic origin, suggesting the hypothesis that Ganymede has undergone greater global expansion than Callisto since the period of high impact flux. P.Y. Huang (MIT) and this author tested this idea by calculating the lithospheric thermal stress that would accumulate from global thermal evolution, including the effects of subsolidus convection and phase changes in H_2O ice, and concluded that Ganymede and Callisto would have had similar stress histories if their initial conditions were similar. If, however, Ganymede began at higher temperatures because of thermal gradients in the proto-jovian nebula[11], the difference in stress histories can account for the different surface characteristics. New estimates of lithospheric thermal gradients versus time in Ganymede and Callisto were reported by Q.R. Passey (Caltech) and E.M. Shoemaker (US Geological Survey) from the distribution of viscously relaxed craters of various diameters and by W.B. McKinnon (University of Arizona) from the widths of concentric ring scarps, interpreted as graben, in impact basin structures. Both studies indicate higher thermal gradients on Ganymede than on Callisto in the period 3 to 4 billion years ago.

The detailed tectonics of grooved terrain formation on Ganymede continue to receive special study. M.T. Zuber (Brown University) estimated the displacement that has occurred between large units of cratered terrain on Ganymede under the assumption that concentric arcs of ring structures in different units were formed by a single event; different locations of the centres of curvature for different units suggest displacements of up to 40 deg arc. M.P. Golombek (Lunar and Planetary Institute) derived a limit of one per cent on the increase in satellite radius associated with extension in the grooved terrain on the assumptions that the grooves are graben and that the dip angles of the bounding normal faults are 60° or greater. This limit agrees with that of McKinnon[11] based on the lack of tectonic disruption of Galileo Regio. S.K. Croft (Lunar and Planetary Institute) proposed that grooved terrain is formed by hydraulic fracturing driven by overpressured water during the final phases of global freezing following early differentiation.

Many of the icy satellites of Saturn show extensional features broadly similar to those of Ganymede[12]. S.W. Squyres, R.T. Reynolds, P. Cassen (Ames Research Center) and S.J. Peale (University of California, Santa Barbara) drew particular attention to Enceladus, which shows features similar to the grooves of Ganymede and large areas of low crater density. Resurfacing of such younger areas could occur either by extrusion of fresh material or by complete relaxation of topography due to a high thermal gradient. A new model by D.J. Stevenson (Caltech) for magma migration by crack propagation through the lithosphere, when applied to Enceladus, suggests that volcanism may occur by comparatively infrequent eruptions of large volumes of H_2O–NH_3 fluids, lending support to the volcanic resurfacing hypothesis. Squyres and his colleagues showed that tidal dissipation is an adequate heat source for volcanism on Enceladus as long as a forced eccentricity several times higher than the current value existed continuously or episodically through a substantial part of its history.

As the data from Pioneer, Venera and Voyager missions continue to be analysed, hypotheses for the evolution of Venus and of the outer planet satellites will be refined. To test these hypotheses will require new spacecraft observations. The US Galileo mission to Jupiter will help provide data for the jovian satellites, and the Soviet Union has announced plans for additional landers to be sent to the Venus surface to conduct further chemical analyses and imaging experiments. A major gap in our knowledge of Venus, however, is a global map of the surface at sufficiently fine resolution to distinguish among the proposed hypotheses for the tectonic evolution of the planet. While the proposed Venus Orbital Imaging Radar mission has fallen victim to reductions in the NASA planetary programme budget, a less ambitious and less costly Venus radar mapping mission is currently being considered to fill this gap. Completion of such a mission would provide a major step towards a full understanding of the evolution of Earth-like planets. ☐

The Middle Awash Valley, Afar, Ethiopia, contains a sedimentary sequence that is >1 km thick, spans much of the Neogene, and contains vertebrate fossils throughout . Newly defined formations described here are older and younger than the hominid-bearing Hadar Formation. The Awash deposystem reflects deposition in an evolving triple junction.

THE Awash River Valley in the Afar Depression (Fig. 1) is unique for containing a 'triple junction river'[1], and, as reported here, a sedimentary record >1 km thick (Fig. 2) that spans much of the Neogene history of the region, including the final breakup of Afro-Arabia. Fossil remains occur throughout the sequence, including those of early hominids. Either hominid fossils or artefacts occur throughout >0.5 km of strata, from the lower Pliocene levels at Hadar[2] to Pleistocene strata at Bodo[3,4] and Andalee[5] (Fig. 2).

This report is based on six seasons of fieldwork with intervening studies by the Rift Valley Research Mission in Ethiopia[1,3–9] (RVRME), under the direction of one of us (J.K.), from early 1975 to mid-1978. Geological investigations are reported below. The accompanying article[10] will report palaeontological and archaeological findings as well as the age of the deposits.

The area studied lies between volcanic plateaus within the Middle Awash Valley (delimited at Awash Station and Tendaho) between Gewani village and Hadar (Fig. 1). Previous geological work in the area is limited to preliminary geological mapping along the SE margin of the area[11,12], observations near Gewani[13], studies at Hadar[1,14,15] and photogeology[13,14,16].

The area studied by the RVRME extends from Gewani to 10°57'N (Fig. 3). The area was geologically mapped from 1:60,000 air photos. This includes the area north to Hadar (from studies by J.K. and D.P. in 1972–73 and traverses by J.K. and A.M. in 1975–76). Extensive base map preparation (aided by H. Mosca and W. Singleton) preceded field surveys. Some 120 geological profiles taken in the map area are referred to in Figs 4 and 5 and in the text by profile numbers (P.1,2,3, and so on); elevations are estimated from published sources[17]. Geographical names are from Afar inhabitants (those in quotation marks are provisional).

The map area (Fig. 3*a*, *b*) lies within a northeastward-drained trough bounded to the west by the Ethiopian Escarpment made up largely of the Miocene 'Fursa basalts'[18], and to the east by a basalt plateau comprised of the Pliocene 'Upper' Afar Stratoid Series[19,20] (UASS). The south-central area (Fig. 3*a*) is capped by basalts of the 'Lower' Afar Stratoid Series (LASS). This central area is complexly faulted and referred to as the Central Awash Complex (CAC) (Fig. 3*a*); it contains the 'Hatowie Graben', bounded by the 'West Hatowie Horst' (WHH) and the 'East Hatowie Horst' (EHH).

The map area forms a northward-dipping structure (due to greater subsidence towards the triple junction) with margins blockfaulted towards the central part of the basin and to the north: older strata crop out to the south along basin margins and the CAC (Figs 3, 5). Dips are greatest at basin and graben margins (or zones of maximum uplift), generally in older strata, and are least pronounced in Pleistocene deposits. Fault trends generally conform to the NW–SE Ethiopian (East African) Rift trend (Fig. 1). Closer inspection reveals the NW trend becomes generally more westerly to the north, and the NE trend more easterly to the south (Figs 3*a*, *b*), a reflection of the rotational movements of the Arabian and East African plates (see refs 21, 22).

Typical badland topography in the area forms exposures up to 20–40 m along basin margins to the south, up to 15–20 m on the EHH, and 90–100 m to the north, where strata are deeply incised by the Awash River.

Stratigraphy (Awash Group)

Stratigraphical studies to date are contained in reports to the Ethiopian Government, in regional, site or faunal descriptions[1,4–9], or will shortly appear in monographic form[23]. Below we summarize the studies and provide the first regional stratigraphical framework for the Middle Awash, as well as briefly describe individual stratigraphical units. [For reference, the Mio-Pliocene boundary is established at 5 Myr (ref. 24), the Plio-Pleistocene boundary at about 1.6 Myr (ref. 25) and the middle Pleistocene boundaries at about 700,000 yr and 125,000 yr (ref. 26).]

The Awash Group is defined here as all late Cenozoic continental sedimentary strata within the catchment of the Awash River. As described below, its known thickness is >1 km thick, and includes the late Miocene Chorora Formation[27] on the SW Hararghe Escarpment (Fig. 1) and the Pliocene Hadar Formation[2], and the presently-described Adu-Asa, Sagantole, Matabaietu and Wehaietu Formations (Fig. 2).

Adu-Asa Formation: Estimated to be late Miocene to early Pliocene[8,10], with a minimum thickness of 145 m; it is best exposed in the SW map area (Fig. 3*a*), between 725 and 825 m a.s.l. (above sea level), and in the CAC from ~640–660 m a.s.l. Adu refers to Adu Dora (white place stream); Asa refers to Asa Koma (red hill). Units comprising the formation (from bottom to top) are the Adu, Asa,and Kuseralee Members (Fig. 2).

Adu Member: At least 40 m of strata either in fault contact or unconformable with the 'Fursa basalts'[18] (P.2,3). The lower unit, especially prominent at upper Ananu and Adu Dora N. (P.3,4), consists of up to 30 m of variegated, predominantly pinkish clays and silts with some variable, cross-bedded sands (up to 2.5 m) and yellow-green clays. The upper unit consists of 12 m or more of massive diatomites (up to 2–3 m), white,

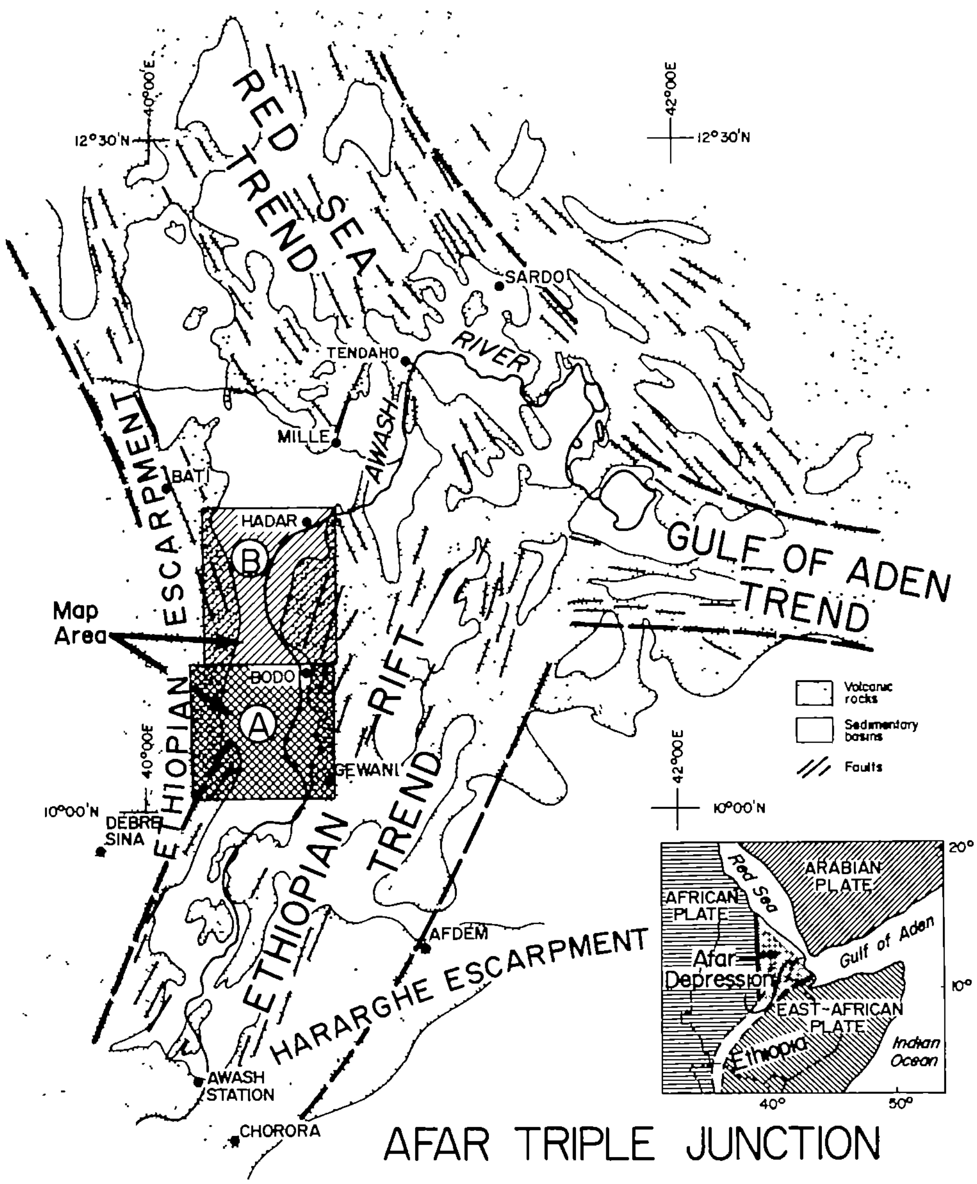

Fig. 1 Study area location map.

indurated clay with some fish bones, reddish-brown clay, and some grey, laminated tuffs.

Asa Member: At least 75 m of strata overlying the Adu Member. The base of the lower unit is marked by either an erosional surface containing distorted bedding and gravel lenses (P.4,6) and/or prominent tuffs. At Asa Hill (P.5), this unit consists of up to 33 m of waterlain well-stratified tuffs (1–3.5 m thick), reddish-brown clays, some coarser layers and minor diatomite lenses. At Adu Dora N. (P.7), the upper unit consists of 30–40 m of predominantly reddish-brown clay, with discontinuous sand (up to 1.2 m), silt and thin tuff layers. Elsewhere, this unit may be overlain by (LASS?) basalts or unconformable alluvium. Fossiliferous strata that may be equivalent to this member exist at Saitune Dora (Fig. 3*a*).

Kuseralee Member: Up to 30 m of strata beneath the LASS basalts, especially at Kuseralee and elsewhere along the margins of the Hatowie Graben (Fig. 3*a*). The stratigraphical position of this unit to the Asa Member is based on its downfaulted lower altitudinal, central position in the basin (P.9,13) and by its more derived fauna. Between Kuseralee and Koba-ah Streams (P.12,13) are up to 30 m of mauve to pinkish tan, sometimes grey, clays with some silts and channel sands and sandstones (up to 3.5 m). Clays form a baked contact zone subjacent to the basalts. Equivalent strata may occur in the eastern Awash between Asaberi and As Streams (Fig. 3*a*), beneath thick (LASS?) basalts (P.61).

Sagantole Formation: Estimated to be early Pliocene[8,10], with a thickness of 210–226 m (Fig. 2) overlying the LASS basalts. Best exposed in the eastern CAC between 757 and 660 m a.s.l. (Fig. 3*a*, 5). We divide this formation into the Haradaso and Aramis Members and two informal units, the Beearyada and Kalaloo beds (Fig. 2).

Haradaso Member: From 71 to 76 m. The lowest strata preserved on the LASS basalts may be in down-faulted structures on the EHH at Haradaso (P.14) and elsewhere. Here are 10–15 m of predominantly reddish-brown and grey clays, with some silts, sands and vertebrate remains[10]. The main unit is in depositional (locally conformable?) or fault contact with the eastern CAC basalt margin and extends 1–2 km eastward between Aramis and Sagantole S. Streams (P.16,17). Here up to 61 m of strata consist of four sand and clay units. Sands are 2.5–6.5 m thick, dominantly fine- to medium-grained, may be laminated or contain coarser lenses, but are commonly homogeneous and interdigitated with tan, reddish-brown or grey clays, silt and shale (with fish remains). At mid-sequence, a lignitic or carbonaceous shale (5–10 m) (P.16,17) exists within a grey (partly tuffaceous?) clay. Upper sands are brown, contain coarser layers, and are associated with brown clays and silts. Equivalent strata in the eastern Awash may exist between Sibabi and Asaberi (P.62,64) overlying (LASS?) basalts, and at lower Wẹe-ee (P.65).

Aramis Member: At least 50 m of strata unconformable or in fault contact (?) with the Haradaso Member (P.18,20). This unit is distinguished by the first major appearance of tuff, which occurs throughout this (and overlying) units. At Sagantole S. are at least 50 m of: (1) tan silts (12.5 m) with siltstones and tuffs (up to 1.75 m); (2) tan, orangish silt (24 m) with sand and tuff layers—upward becomes increasingly sandy (up to 88 m) with gravel lenses; (3) light tan silt (11 m) with sandstone lenses. Equivalent beds in the eastern Awash may exist at lower Wee-ee (P.65).

Beearyada beds: Thickness ~75–85 m (exact values are unknown owing to faulting). Between Aramis S. and Sagantole N. (P.20,23), these beds conformably overlie the Aramis Member and consist of: (1) well-bedded yellow tuffs (4 m+) (P.20); (2) pinkish to tan silts with grey, well-stratified, laterally continous tuffs (2 cm–1.5 m), and some sand, sandstone and clay (30–40 m); (3) at Beearyada, tan silt and sand below and coarsening upward sand and conglomerate above (11.5 m); (4) repeat of (2) above (5.3 m); (5) brown clay, silt and some sands, tuff and brown mudstone (15–18 m). These beds are capped by laterally continuous, gastropod limestone layers (P.23). Strata possibly equivalent to the upper part of this unit in the eastern Awash lie below a widespread gastropod limestone between Kalaloo and Bodo Streams nearest the basalt (P.24,25), and south (Fig. 3*a*).

a

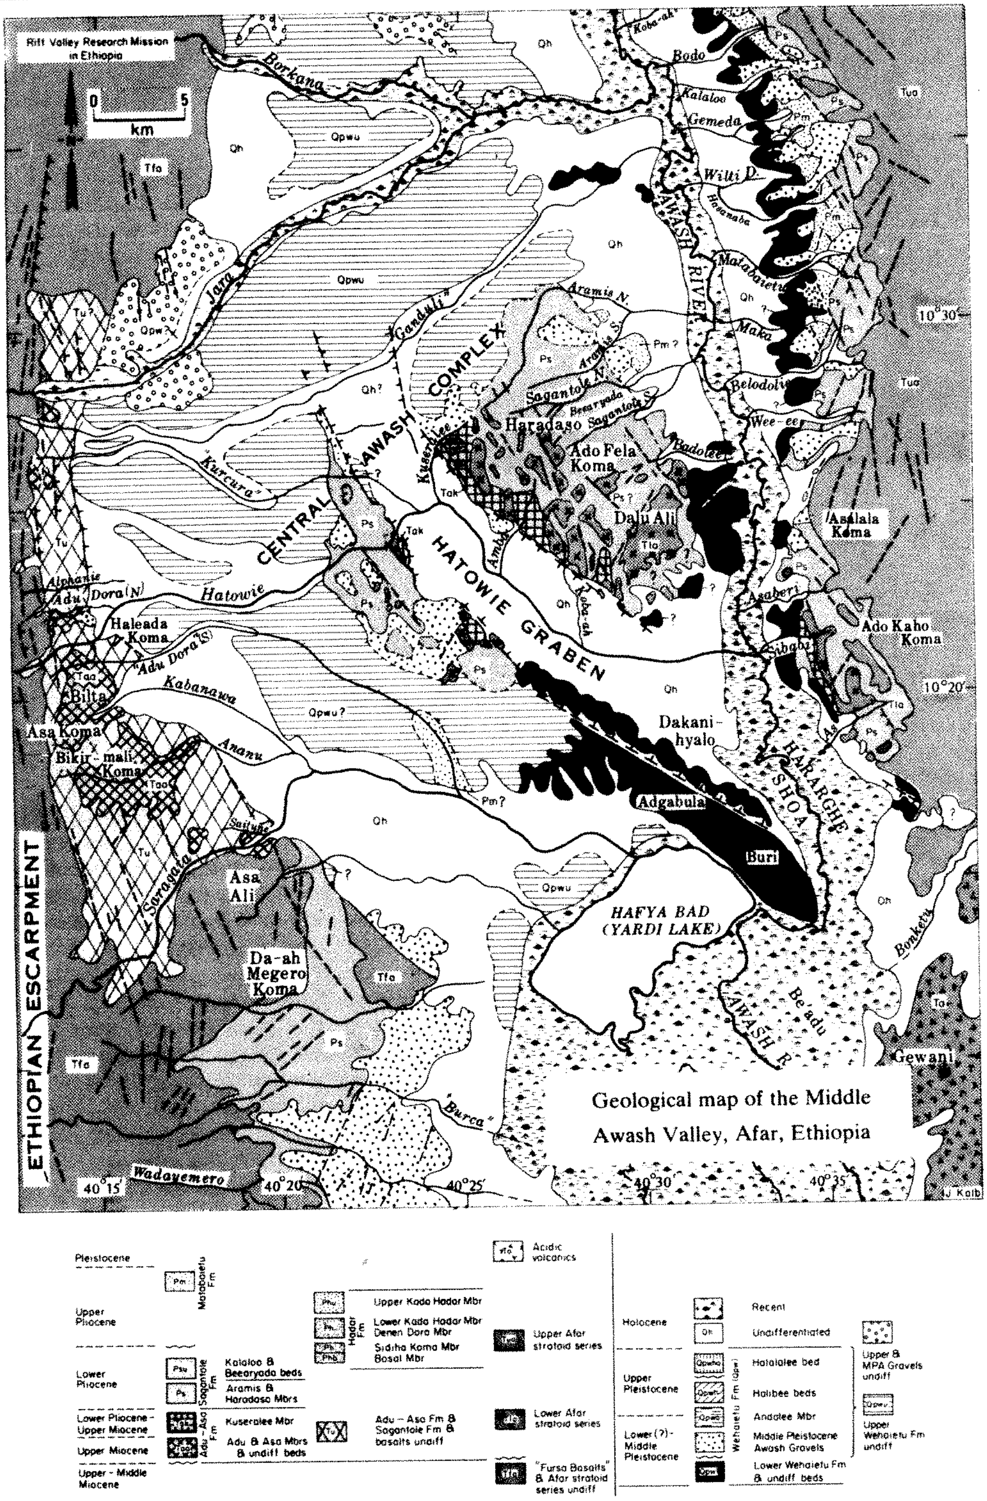

Fig. 3 *a*, Geological map of the Central Middle Awash Valley (southern sector). *b*, Geological map of the Central Middle Awash Valley (northern sector).

Kalaloo beds: A minimum of 14–15 m of strata. Overlying the gastropod limestone (P.24–26)/between Kalaloo and Bodo Streams, the base is marked by a widely traceable coarse or lapilli tuff (10–35 cm), followed by a variable sequence of tan silts with siltstone, sand, and microconglomerate lenses, with grey and brown clay upwards. Several tan, silty tuff layers (0.5 m to 3.5 m in a channel at mid-sequence) are present. Some disconformable strata may exist in the upper portion.

Hadar Formation: Predominantly middle Pliocene[10,28,29], and up to 270 m thick, this unit crops out well north of the Sagantole Formation (Fig. 3*b*), and, because of regional subsidence, at lower elevations (P.40,48). If physical correlation is possible betweeen the Hadar and Sagantole Formations, it would probably require tracing the Kada Damoumou basalt[30] (P.46) to basalts further south that intercalate the Sagantole Formation. The Kada Damoumou basalt seems to correlate with basalt to the SE; correlation further south is complicated by erosion of overlying beds, and intervening faults and younger beds. Basalt in a stream-bed ~5 km SW of the Ounda Meshellu–Awash confluence appears to lie at the base of the Hadar Formation (P.40) (Fig. 2).

Upper Hadar Formation (UHF) beds, undifferentiated: At least 50 m thick, these beds crop out north of Hadar in the drainages of Ledi, Geraru and Weranso Streams and the Mile River[14,15]. These beds, first surveyed in 1971–74 by three of us (J.K., D.P., E.O.), and in part by Taieb[14,15], occur downdip to

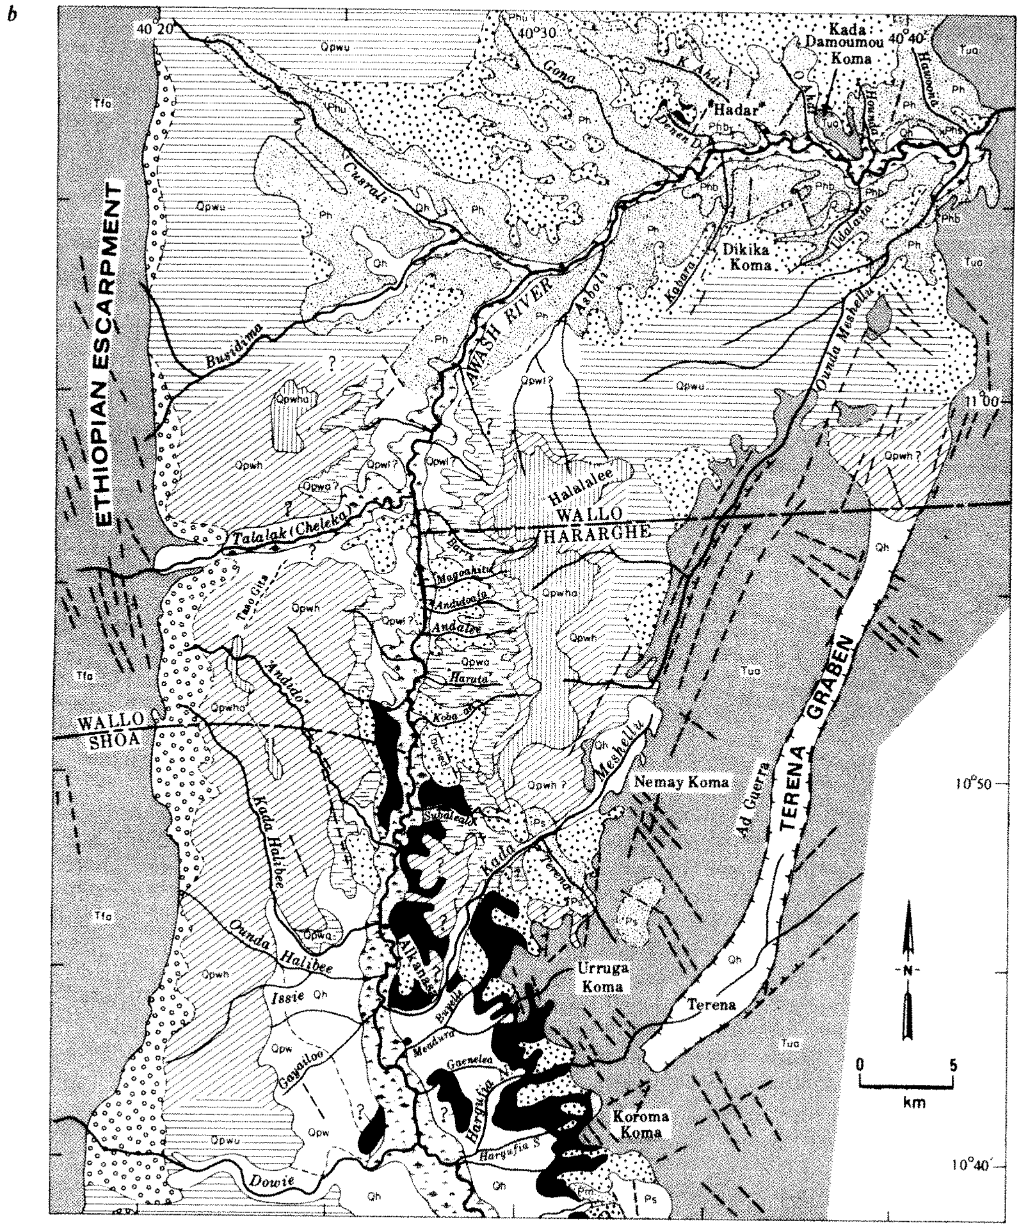

Fig. 3 (*cont.*)

or are downfaulted in relation to the Hadar Formation (P.48). They are broadly similar to the described strata in the upper Hadar Formation, but contain fauna associated with younger units[10].

Matabaietu Formation: Late Pliocene[10], at least 52–57 m thick (Fig. 2), and best exposed in the eastern Awash (Fig. 3*a*). In fault contact or unconformable with the Sagantole Formation (P.70,73). At Matabaietu, the lower unit consists of 34–39 m of up to three variable, discontinuous, cyclic units of clay, sand and tuff deposition. At the base are predominantly reddish-brown clays (23–28 m thick), with some mottled darker clay. Sands (up to 2 m) are irregularly bedded, calcareous and contain gravel lenses, cross-beds and plant casts. Tuffs are up to 2.5 m, sandy or silty, reworked, well-weathered and contain gravels, plant casts and limestone concretions. The upper tuff, from which an Oldowan chopper was recovered[10], is referred to as the 'chopper tuff'. The upper unit (14 m) outcrops west and updip from the chopper tuff, which it appears directly to overlie, although a fault contact is possible. Strata consist of: tan and grey clays (12 m) with small concretions and plant casts; argillaceous tuffs with plant casts; and some microconglomerate lenses. The unit is capped by up to 4 m of (unconformable?) pebble conglomerate and minor brownish-grey clay. Similar strata exist in the uppermost levels of Hadar and in the UHF beds. Based on faunal considerations, the upper UHF beds may be of similar age[10].

Bikirmali beds: Up to 30–40 m or more of poorly-sorted tuffaceous alluvium truncate the Asa Member at Bikirmali Hill (P.6) (Fig. 2*a*) and elsewhere. The stratigraphical position of these beds is uncertain; however, a late Pliocene age is inferred by fragmentary vertebrate remains (*Hexaprotodon*, progressive *Elephas recki*)[10]. Basic basalts (7–8 m) cap the sequence.

Lower Pleistocene (?) Awash conglomerate: It may be that only minor deposits document the period between the Matabaietu Formation and the Bodo Member (Wehaietu Formation). Their faunas clearly show the age difference between these two units[10]. Missing strata may be explained by faulting, and in part by erosional episode at the end of Matabaietu deposition, which may possibly be recorded by uppermost conglomerates at Matabaietu and Bodo; north of Hadar, conglomerates cap the UHF beds at various localities, perhaps the most prominent being at As Hill, 15 km NW of Hadar. Here massive (4–6 m thick), resistant conglomerates, some 35–45 m above the surrounding plain, truncate the UHF beds,

Lower (?) to Middle Pleistocene beds, undifferentiated: At Wilti Dora, a 3–4 m waterlain tuff overlies the Matabaietu Formation unconformably and is downthrown to the west by a normal fault. This tuff contains some fossils, including: *Kolpochoerus* sp., hypsodont *Hippopotamus* sp. and *E.* cf. *recki*, and the first appearance of *Equus* in the Awash Group. West of and apparently overlying the 'Equus tuff' are >14 m of largely unfossiliferous brown clays, with some conglomerate layers that extend southward and may be the same as sediments (estimated at 20–30 m thick) west of the conglomerates capping the Matabaietu Formation at Matabaietu. At Bodo, as at Wilti Dora, a thick tuff (Equus tuff?) appears to overlie the Matabaietu Formation unconformably and is offset by faults. Fossils from this tuff are *Equus* and a large *Theropithecus* (similar to a robust form from the Bodo Member) (C. Jolly, personal communication).

Wehaietu Formation: Early (?) to late Pleistocene[10], with an estimated thickness of 200–250 m. Exposed throughout the map area (Fig. 3*a*, *b*), between 500–650 m a.s.l. (Fig. 5). Wehaietu is a name in the Afar language used interchangeably for the Awash River. This formation is divided into (from bottom to top): the Bodo, Meadura, and Dakanihyalo Members, the MPA Gravels, the Andalee Member, and the informal Halibee beds (Fig. 2). The MPA gravels divide the formation into two readily distinguishable larger units, the lower and upper Wehaietu Formation.

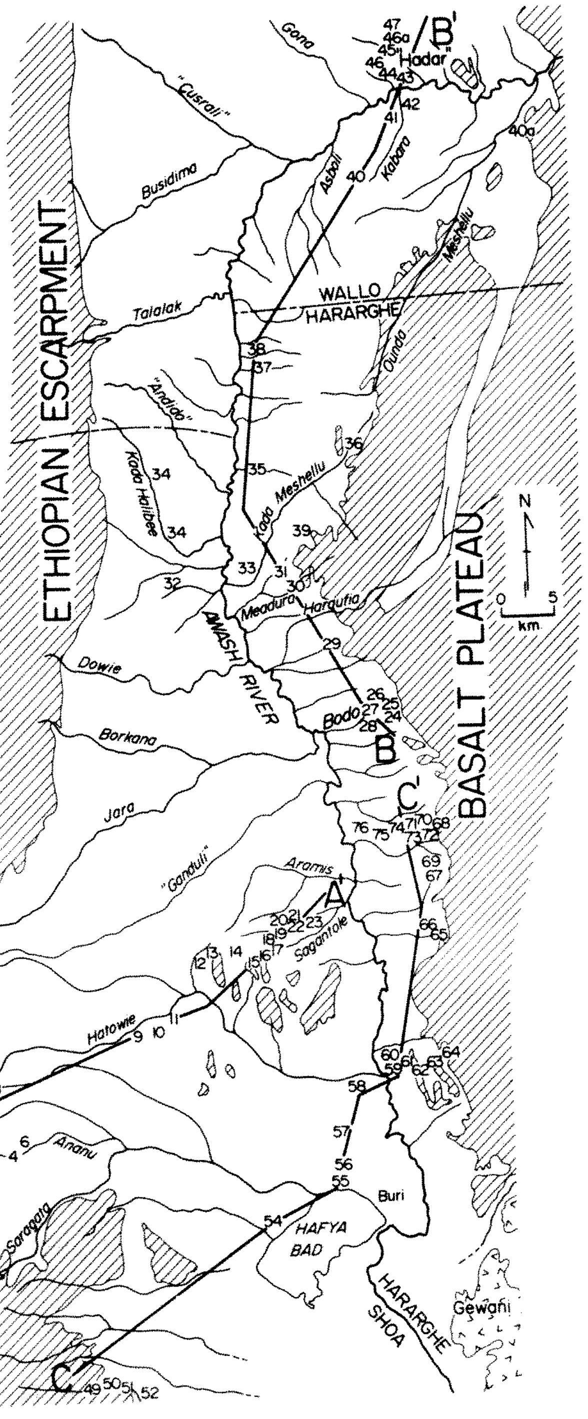

Fig. 4 Geological profile index map.

Bodo Member: At least 16–19 m of strata between the Bodo and 'Koba-ah' Streams (Fig. 3*a*, *b*). The base of the member, as presently defined, consists of the previously-described Upper Bodo Sand Unit[4] (UBSU) (P.28) that unconformably overlies thick, reddish-brown clays (Matabaietu Formation). Acheulian artefacts and fossils, including an archaic *Homo* cranium[3], are abundant throughout the lower half of the unit[10]. North of Bodo, the USBU is overlain by brown clays containing (barring any intervening faults) tuff lenses that wedge out to the west.

Meadura Member: A minimum of 45–50 m of strata between Hargufia and Meadura Streams (Fig. 3*b*). These strata have not been correlated directly with the Bodo Member because of intervening alluvium; however, because of lithological differences, the northward regional dip (almost certainly placing the Meadura beds higher stratigraphically) and faunal distinctions[10], these strata are treated as a separate unit. At Meadura, the lowermost strata may be those to the far east, altitudinally higher than the main (downfaulted?) outcrop areas to the west, in marginal grabens, and in adjacent areas to the south. To the west, a minimum of 35 m strata lie unconformably against basalts, or are downfaulted. Lithologies exhibit considerable lateral facies variation and are dominantly brown (sometimes mottled grey) and tan clays, tuffaceous silts and tuffs (0.6–1 m); fine- to coarse-grained sands (1–4.6 m) with gravel lenses; and poorly-sorted sandstone conglomerates (0.7–1.4 m). Tuffaceous deposits are concentrated in the upper sequence, as is abundant calcium carbonate material. The latter includes spheroidal stromatolite boulders (up to 1.5 m in diameter) with laminations and micro-structure similar to bacterial stromatolites (R. L. Folk, personal communication); these can be traced southwards to Hargufia[4]. Strata are broadly similar at Hargufia but may extend lower stratigraphically (P.29,30).

Middle Pleistocene beds, undifferentiated: Estimated 25–35 m of strata. At Buyelle (P.31), the Meadura Member is overlain by at least 15 m of predominantly orangish-brown, fine-grained sediments that abut basalts (Fig. 3*b*). Between 'Alkanasa' (P.33) and 'Subalealo' (P.35) are a minimum of 10–15 m predominantly sandy sediments with tuff layers. Thick, well-bedded tuffs, tan silts and clays occur at the base of the Subalealo sequence; to the north, these beds appear truncated by the MPA Gravels; immediately south, they may be overlain unconformably by the upper Wehaietu Formation (?). Fauna from Subalealo is consistent with that in the Meadura Member. In the Hadar area, terraces wedged between the Hadar Formation and the MPA Gravels, bearing Acheulian tools[31,32] (P.46a), may be assigned to the lower Wehaietu Formation.

Dakanihyalo Member: At least 15–20 m of strata that occupy the SE portion of the WHH (Fig. 3*a*). The higher stratigraphical position of this unit relative to the Meadura Member is inferred by its central and generally lower altitudinal position (P.56,57) in the Awash basin, and its associated fauna[10]. At Dakanihyalo and to the west, sediments are commonly buff and reddish-brown discontinous beds dominated by medium to very coarse, cross-bedded sandstones (locally up to 5 m thick), and pebble conglomerates, with silt and clay interbeds.

Middle Pleistocene Awash Gravels: 1–4 m thick, these gravels are ubiquitous in the Middle Awash[31] (Figs 2, 3*a*, *b*) truncating the lower Wehaietu Formation or older units. They are named the MPA Gravels to distinguish them from late Pleistocene and Holocene gravels[33] as well as from older gravels. Their relationship to surrounding units is best seen between Ounda Meshellu and 'Barre' Streams (Fig. 3*b*).

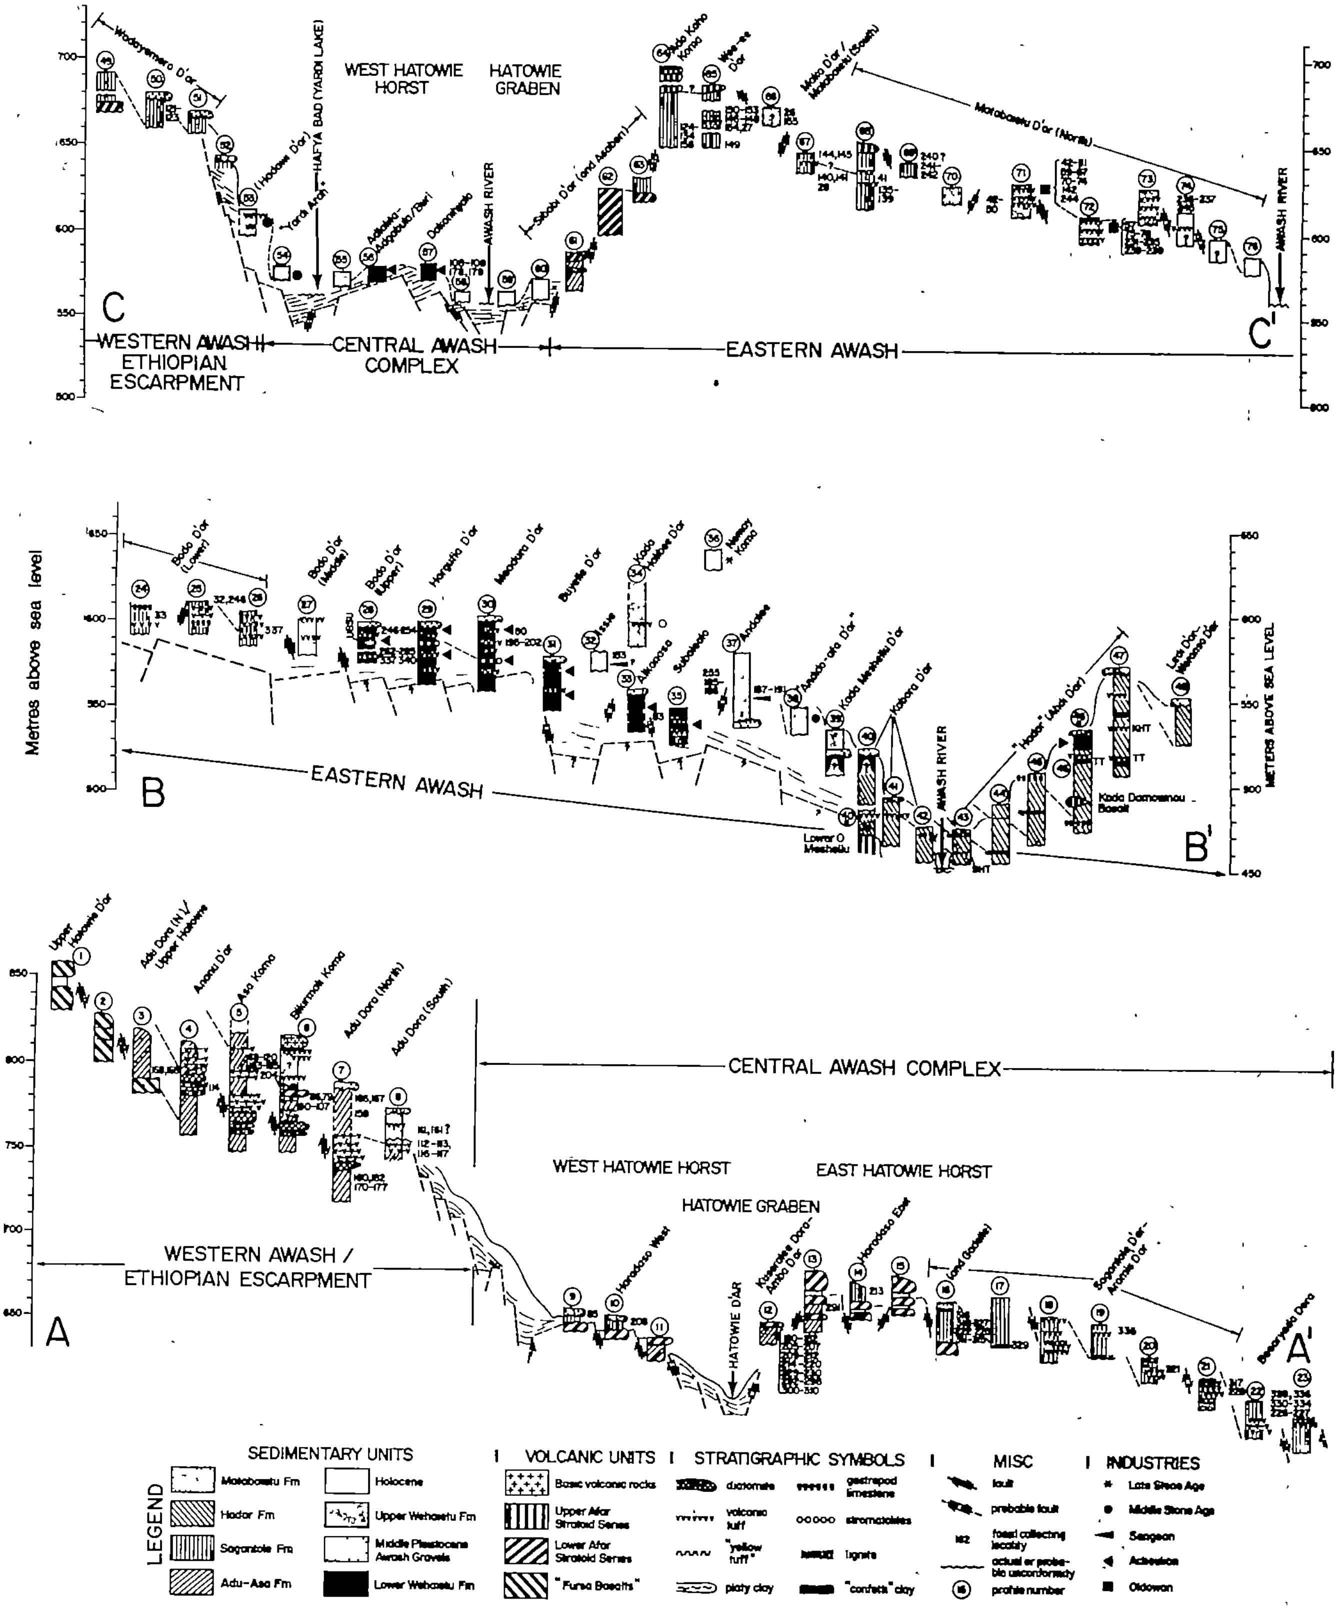

Fig. 5 Composite geological profiles of the Middle Awash Valley.

Andalee Member: Estimated to be a minimum of 55–60 m thick. In the northern map area (Fig. 3*b*), these strata appear to onlap progressively the northward-dipping MPA Gravels, forming an unconformable wedge that thickens to the north (and in the central part of the basin). At Andalee, a preliminary assessment of the local geology has been made[5]. The lower sequence rests on the MPA Gravels (P.37) and consists of 6–8 m of sand, silt and clay interbeds with calcified concretions, microconglomerate lenses, and a rich concentration of very small- to medium-sized vertebrates, associated with a Sangoan-like tool industry[5,10]. The upper sequence is >34 m thick and consists of massive brown clay and silt with cross-bedded sands and gravel lenses.

At Issie, in beds that appear to lie just below the basal tuff (?) of the Halibee beds, is another locality rich in very small- to medium-sized vertebrates associated with a diverse tool industry[5,10]. These are contained within 2–3 m of tan loosely-consolidated silts and clays with minor sands.

Halibee beds: Estimated to be up to 35–45 m of strata conformable with the Andalee Member (P.34), as best observed between Kada Halibee Stream and the Talalak River (Fig. 3*b*). These beds are undifferentiated and informally defined. Generally, at the base seems to be a widely traceable tuff layer, overlain by predominantly light-coloured, fine-grained, loosely-consolidated sediments containing some tuffs and darker clay, sand and gravel layers.

Halalalee bed: Mantling the Halalalee plain (Fig. 3*b*), at the top of the Halibee beds, is 1–2 m of unconformable, dark-brown and grey clayey layer that may be a palaeosol. Only remnant patches of this bed occur in the western Awash, overlaying the upper Halibee beds.

Holocene beds: Deposits that postdate the Halibee beds, and contain late Stone Age artefacts[10] and vertebrate remains, occur throughout the Middle Awash (Fig. 3*a*, *b*) at progressively lower altitudes, between ~645 and 490 m a.s.l. At Nemay Koma, in the uppermost catchment of Kada Meshellu Stream (Fig. 3*b*) (P.36), between ~630 and 645 m a.s.l., are at least several metres of predominantly tan fine-grained sediments unconformably overlying Pliocene basalt and strata. Along the SE margin of the map area near Gewani (Fig. 3*a*) are 4–8 m of deposits that represent a lake terrace at least 575 m a.s.l. These deposits are diatomaceous and rich in calcium carbonate and stromatolitic material[13]. At Mero Buri, south of Hafya Lake some 14–16 km, are 3–4 m of light-brown silts and sands occurring several metres above the modern Awash floodplain.

Palaeoenvironments

The base of the late Miocene Adu-Asa Formation is marked by fluvio-lacustrine deposition in the lower Adu Member. Massive diatomite formation in the upper Adu Member indicates distinct lake development. The end of the Adu period is marked by erosion (localized?) and an abrupt onset of massive tuff deposition in the Asa Member, probably associated with widespread volcanic (and hydrothermal) activity, regional subsidence and an eastward migration of lacustrine deposition. This period may have coincided with or slightly preceded one of widespread tectonism and renewed spreading in the southern Red Sea in the late Miocene[35].

The thickness and stratification of the tuffs in the Asa Member combined with minimal diatomite formation and fluvial layers, indicate that the Adu-Asa lake environment probably entered a period of instability, decreasing depth and increasing fluvial influences. The upper Asa Member suggests a return to alluvial conditions and a tapering off of volcanic activity. The Kuseralee Member indicates predominantly fluvial deposition; this was interrupted, and the Adu-Asa Formation sealed, by massive extrusion of LASS basalt lavas during the latest Miocene to earliest Pliocene[10].

Strata comprising the bulk of the Haradaso Member suggest a dominantly progradational depositional pattern (lake margin, marsh, stream) that may reflect adjustments to regional subsidence. The Aramis Member and Beearyada beds appear dominated by shallow and marginal lacustrine environments, with episodes of fluvial and fluvio-deltaic deposition; the Kalaloo beds indicate predominantly lake margin and alluvial deposition. Tuffs throughout these units indicate continuous volcanic activity, as do intercalated UASS basalts.

The Hadar Formation generally reflects a northeastwards migration of the Awash deposystem during the Pliocene, indicated by a pattern of basin expansion at Hadar during the middle Pliocene, and progradation in the late Pliocene (cf. ref. 28). This accompanied the well-documented period of extensive graben development and subsidence in the central Afar during the Pliocene (see refs 21, 22).

The predominantly fluvial deposits in the upper Hadar Formation also appear dominant in the UHF beds and the Matabaietu Formation (and the Bikirmali beds) and point to a prolonged period of alluviation and some downcutting in the late Pliocene, accompanying a change in base level, tectono-volcanic activity, an eastward migration of lacustrine deposition (especially evident at Geraru[15]) and generally drier conditions. This period may have been followed by a major episode of clastic deposition and erosion in the early Pleistocene.

It is clear that by the time of deposition of the lower Wehaietu Formation in the early (?) to middle Pleistocene, the Middle Awash had undergone major structural and geomorphic changes with deposition concentrated at distinctly lower elevations and further north. Whereas the fluvial deposits at Bodo[4] and the Acheulian tool-bearing terraces at Hadar indicate alluviation and downcutting, the calcium carbonate-rich deposits and stromatolites stretching from Hargufia to Meadura indicate a period of widespread transgressive lacustrine deposition. The texture of the stromatolites suggests bacterial growth enhanced by geothermal waters (see, for example, ref. 36); their spheroidal shape suggests a lacustrine setting similar to that described for stromatolites near Lake Turkana[37]. Strata overlying the Buyelle–Alkanasa beds, including the Dakanihyalo Member, suggest predominatly fluvial deposition. Associated tuffs throughout the lower Wehaietu Formation indicate continued volcanic activity, probably from silicic centres near Gewani[19,20] and elsewhere; likewise, faults and tilted strata indicate tectonic activity.

The MPA Gravels indicate major peneplanation and extensive downcutting during an apparently prolonged and major dry period, probably during the late-middle Pleistocene[38]. At this time, strata were heavily eroded, and an extensive, northward-sloping pediment was created, such that the upper Wehaietu Formation onlapped the MPA Gravels from north to south. The lower Andalee Member (and its associated fauna) suggests deposition initially occurred in a sub-arid environment much like the modern Awash Valley[5]. Following deposition of the Halibee beds and continued tectono-volcanic activity, the Awash was again subjected to regional downcutting. This began apparently at the end of the Pleistocene and continued during successive dry periods during the Holocene (compare with refs 33, 34, 38). Intervening wetter periods seem to be indicated by (lacustrine?) deposits at Nemay Koma and near Gewani. Those near Gewani are equivalent in age to transgressive lake deposits described in the central Afar[13,33]. An early Holocene lake in the Gewani area would extend possibly over much of the depressed area extending from Sibabi to the basalt plateau 44 km to the south (Fig. 3*a*).

The palaeogeography of the Middle Awash indicates a deposystem that has continuously migrated towards lower and more northeasterly positions from the late Miocene to the present. Basin development was in concert with subsidence and rotation of host structures controlled by crustal attentuation and plate movements in the triple junction. This interaction of deposition with tectonics is reflected in the movement of lake basins to the NE, as well as by major changes in base level that amplified the effects of erosion and downcutting during dry periods.

A review of fossil mammalian faunas from the Middle Awash indicates they span most of the later Neogene and document evolutionary change in several mammalian groups, especially Primates, Proboscidea and Artiodactyla. Oldowan artefacts first appear in the late Pliocene, while Acheulian and later industries and apparent occupation sites occur in Pleistocene beds.

INVESTIGATION of the Middle Awash deposits by the Rift Valley Research Mission in Ethiopia[1,2] (RVRME) resulted in the documentation of 333 fossil localities and hundreds of archaeological occurrences. Fossil and artefact localities were plotted on air photographs (1 : 60,000) and/or site maps (1 : 6,000) and in stratigraphical sections that permitted them to be precisely located geographically and inserted in the regional geological sequence. Detailed locality maps and reports were submitted to the Ethiopian Government[3,4].

Approximately 2,500 fossils were collected and studied in the Ethiopian National Museum and the Paleobiology Research Laboratory at Addis Ababa University. Only limited samples of artefacts were recovered. Fossils and artefacts are stored in the Ethiopian National Museum. Many additional fossil specimens, especially skulls of large ungulates that were too bulky to be collected with the resources at hand, were left *in situ* (and often photographed) for future collection. When added to the previously described data from the Hadar Formation, these collections provide a biostratigraphical sequence that documents long stretches of the evolutionary history of the Middle Awash fauna since the late Miocene.

Fauna and biostratigraphy

Mammalian taxa identified in the collections are systematically listed in Table 1 and are designated according to stratigraphical unit. Table 2 provides the distribution of major taxa according to the order of their first appearance in the regional sequence, inclusive of taxa from the Chorora[5] and Hadar Formations[6,7]. Most work has been carried out on the primates, Proboscidea and Artiodactyla. Previous accounts of the various vertebrate taxa are contained in reports to the Ethiopian Government[3,4], regional summaries[1,8], site reports[9,10], and studies of individual taxa[11–13]. More detailed treatment will be reported elsewhere[14].

Table 1 Systematic faunal list, Awash Group (newly described units only)

- **Mammalia**
  - Chiroptera indet. (As)

Formations: AA, Adu-Asa (inclusive), SA, Sagantole (inclusive); MA, Matabaietu. Sub-units. Ad, Adu; As, Asa, Ku, Kuseralee; Ha, Haradaso; Ar, Aramis; Be, Beearyada beds; Ka, Kalaloo beds, Et, Equus tuff; Bo, Bodo; Me, Meadura, Da, Dakanihyalo, An, Andalee; Ani, Andalee (Issie). Other· Provisionally assigned units in quotation marks.

The age of the Middle Awash units and their relationship to the wider African late Neogene biostratigraphical sequence can be estimated from their stratigraphical relationships and the composition of their faunas. These data are compatible with the few radiometric dates presently available from the Middle Awash. We anticipate that additional radiometric and palaeomagnetic data will provide a stronger chronological framework in the region.

The Chorora Formation is bracketed by radiometric dates of 10.5 and 9 Myr[5], and its fauna bears resemblances to that of the Ngorora Formation[15]. The Fursa basalts, which underlie the Adu-Asa Formation, are dated at 10–12 Myr[16]. The Lower Afar Stratoid Series (LASS) basalts[2], which immediately overlie the same formation, are as yet undated, but they (and the underlying Adu-Asa Formation) are clearly older than the Upper Afar Stratoid Series (UASS) basalts, whose maximum age is 4.4 Myr[17]. The Adu-Asa fauna is comparable with assemblages from late Miocene units in the Baringo basin—the Mpesida beds (±7 Myr), the Lukeino Formation (±6.5 Myr) and the Kaperyon Formation (±5 Myr)—and to the fauna from the Lothagam-1 beds[18–23]. The latter is conventionally dated to ±5.5 Myr[20]. More precise affinities of each member can be suggested, particularly based on Suidae and Probosicidea, although these must be regarded as hypothetical.

The faunas of the Adu and Asa Members both include a very primitive nyanzachoerine that has been referred to by Harris and White[23] as *Nyanzachoerus tulotos* and by A. F. Wilkinson (personal communication) as resembling *Bunolistriodon* (=*Kubanochoerus*) *massai*. This suid, together with the presence of *Stegotetrabelodon*, '*Stegodibelodon*', *Primelephas* and *Miotragocerus* suggests that the lower levels of the Adu-Asa Formation may be at least as old as the late Miocene Lothagam-1 beds or perhaps the Lukeino Formation. A late Miocene age is supported by a primitive *Anancus*—the first of four evolutionary stages for this genus in the lower Awash Group—similar to that found in Lothagam-1 (V. J. Maglio, personal communication), *Kobus* cf. *subdolus*, known from Langebaanweg[24], and indirectly by a primitive *Sus*-like suine identified as 'early' *Kolpochoerus* (H. B. S. Cooke, personal communication).

Stegotetrabelodonts are absent in the Kuseralee Member while an apparently more advanced *Primelephas* is present, as well as a primitive elephant retaining features of both *Mammuthus subplanifrons* and *Primelephas*. A more advanced form of *Anancus*, similar to *A. kenyensis*, has replaced that from the Asa Member, while *Nyanzochoerus kanamensis* has replaced *N.* cf. *tulotos*. A bovine similar to *Ugandax gautieri* from the lower Kaiso Formation[25] is present, as is *Mesembriportax*, known from 'E' Quarry, Langebaanweg[24]. A colobine monkey has similarities to *Libypithecus*, known from North Africa[26]. Overall, the Kuseralee fauna suggests a date later than Lothagam-1, but distinctly earlier than Lothagam-3, and very close to the Mio-Pliocene boundary (5 Myr[27]).

Fauna in the Sagantole Formation, which overlies the LASS basalts, is comparable with that of early Pliocene units in the Baringo Basin (lower Chemeron Formation, Aterır beds)[19,23,28], in the Lake Turkana basin (the Lothagam-3[23], Ekora and Kanapoi[20] beds, the Mursi Formation[29]) and, in South Africa, Langebaanweg[13,23,30,31]. Again, some tentative correlations within this span are suggested by the phylogenetically active pigs and elephants. The Haradaso fauna is probably older than Kanapoi, itself capped by a 4-Myr basalt[20]. The fauna of the Aramis Member and Beearyada beds is similar to that of Kanapoi itself, in particular in the combination of an early *Notochoerus* with *Nyanzachoerus jaegeri*, and the first appearance of *Loxodonta*, together with primitive *Elephas*. The Kalaloo beds incorporate more derived forms of two proboscidean lineages, a *Mammuthus* exhibiting features intermediate between *M. subplanifrons* and *M. africanavus* and a very advanced *Anancus* (unlike described species). The cercopithecoid monkey, *Theropithecus oswaldi*, is apparent for the first time, represented by a small and evidently primitive form. Very similar forms of *Theropithecus* and *Mammuthus* are also seen at Hadar (personal communications from E. Delson, and M. Beden).

The age of the Hadar Formation can be estimated at between ~4 and 2.5 Myr on the basis of included basalt and tuffs[32]. Its fauna has been compared with that of the Laetolil Formation (3.7–3.5 Myr), Members A–C in the Shungura Formation (3.0–2.4 Myr), the lower units at East Turkana and the Kaiso Formation[7,23,32–41].

Fauna in the Matabaietu Formation includes many forms absent from the Hadar Formation, and suggest a moderately younger age, and is generally comparable with that of Members D–F of the Shungura Formation (2.4–2.0 Myr)[29,32–39], the Chemoigut beds at Baringo[42], collecting unit 3 in the Koobi Fora Fm, Olduvai below the Lemuta Member[28,35,41] and the upper Kaiso Formation[23,43]. The UHF beds[2] are broadly similar in stratigraphical position and the fauna that they contain.

The Wehaietu Formation is clearly Pleistocene in age. The fauna of the lower units (Equus tuff; Bodo, Meadura and Dakanihyalo Members) may be comparable with Olduvai above the Lemuta Member[23,44], and Olorgesailie[45], while a combination of faunal, stratigraphical and archaeological evidence[2,10] suggests that the upper Wehaietu Formation above the Andalee Member is late Pleistocene, perhaps synchronic with the Abhe I beds of the central Afar[46]. A single ^{14}C date of 8,955±yr BP from the Holocene beds near Gewani[47] suggests that these beds are equivalent in age to lake sediments deposited in the central Afar between 5,000 and 11,000 yr BP[46].

Archaeology

We now provide a regional overview of the RVRME archaeological sites whose individual descriptions or stratigraphical contexts have been presented, or will shortly appear, elsewhere[1,2,9,10,48–50]. An Oldowan-like industry occurs in the lower Matabaietu Formation at Matabaietu[49] and Wilti Dora, where it is associated with large mammals, especially elephants.

		Late Miocene		Late Miocene–Early Pliocene		Early Pliocene			Late Pliocene			Middle Pleis.			Late Pleis.	Present

×, Present; o, most similar or probable form present. Fm, Formation; Mbr, Member.

An early lithic site has also been reported in the upper Kada Hadar Member of the Hadar Formation[51], and two of us (J.K., E.O.) have recorded a diverse Oldowan assemblage in the UHF beds. Archaeological sites in the Wehaietu Formation document middle and late stages in the development of the Acheulian Industrial Complex[1,9,10,48,50]. In numerous localities, artefact assemblages occur in clusters in apparent primary association with the remains of single large- or medium-sized mammals, suggesting butchery sites. At other localities, the occurrence of both tools and debitage suggest tool manufacture. Tools are generally made of basalt, usually identifiable as of local derivation.

Assessment of the total early (?) to Middle Pleistocene Acheulian sequence in the lower Wehaietu Formation reveals that the Acheulian Complex is represented throughout >100 m of stratigraphical section, in an area of >25 km^2. From Hargufia to Subalealo alone, a distance of 20 km, individual tool occurrences are virtually continuous and number in the hundreds, with artefacts in the tens of thousands. In this area, at Bodo, and in the area surrounding Dakanihyalo and Adgabula, there are at least eight separate levels of Acheulian tools representing several distinct stages in the development of the Acheulian Complex. At all levels, tools are associated with faunal remains, often in direct context, suggesting butchery sites or living floors. At least one quarry/factory site is present (at Meadura), and the apparent occurrences of burned bone associated with tools [at Meadura (?), Adgabula] may prove to be among the earliest records for fire use known.

The MPA Gravels are associated with three distinct sets of artefacts. Within the gravels are highly rolled and weathered tools derived from older, Acheulian- (and Oldowan- ?) bearing deposits. Later artefacts occur on the surface of the gravels, derived as lag from the erosion of overlying sediments—a fact that has caused confusion about the age of this deposit[52,53]. Corvinus[54], working at Hadar, was the first to demonstrate clearly the stratigraphical relationship of these gravels to underlying *in situ* Acheulian tool-bearing deposits. Artefacts *in situ* on the surface and, reportedly, also within the MPA Gravels[54] may bear similarities to those from Andalee.

Artefacts from the lower sequence at Andalee represent one of the rare occurrences of an *in situ* 'Sangoan' industry and are associated primarily with very small- to medium-sized mammals[10]. Finally, the assemblage from Issie contains a diversity of retouched, well-formed tools that suggest later industrial influences. Middle Stone Age tools predominate in assemblages elsewhere in the upper Wehaietu Formation. Late Stone Age microlithic tools made from silicic materials occur throughout the Holocene beds, especially at Nemay Koma and Mero Buri. Ceramics occur at several localities on or adjacent to the Awash floodplain.

Discussion

When added to the previously-described Hadar Formation, the stratigraphical sequence running from the Adu-Asa Formation through the Wehaietu Formation provides one of the longest and most complete records of land vertebrate evolution yet recognized in the African Neogene. In particular, the formations and faunas newly described here document faunal evolution immediately preceding the well-known middle Pliocene of Hadar, and provide a uniquely continuous record of faunal, cultural and environmental change during the last half of the Pleistocene.

The faunas of the latest Miocene to earliest Pliocene and Middle to late Pleistocene of Africa are known from scattered sites that in most cases cannot be unambiguously arrayed against a single stratigraphical and chronological scale. Hopefully such a scale should be significantly improved now that the essentials of the stratigraphy of the Middle Awash deposits are known, intercalated as they are with volcanic materials. The collections reported here have already contributed to knowledge of the history of major taxa during this period. Among the Bovidae, for example, are a combination of genera (*Miotragocerus*, *Mesembriportax*, *Ugandax*) known separately from North, South and East Africa[24]. Among the Suidae, the succession of species in the genus *Nyanzachoerus* is documented, as is that for *Kolpochoerus*. The latter includes what may be the earliest African suine in the Adu and Asa Members, a primitive *Sus*-like form which tends to confirm Cooke's hypothesis about the origins of this genus[55]. Advanced kolpochoeres in the Wehaietu Formation provide insights into what may be among the latest representatives of this genus.

The Proboscidea include material that documents extensively some hitherto poorly known taxa. The gomphotheriid *Anancus* occurs throughout the Adu-Asa and Sagantole Formations, throughout >350 m of section. This occurrence is more extensive than any previously described from trans-Saharan Africa, and will ultimately form the basis of a full revision of the group, one of major biostratigraphical importance. At present, the Awash anancines are grouped into evolutionary stages, in the course of which molars become larger and more complex. Stages in the series serve to link sites such as Langebaanweg, Sahabi and Lothagam. Similarly, all recognized genera of Elephantidae are present in the Middle Awash. These include stegotetrabelodonts, as well as a variety of true elephantines that particularly document early stages of diversification of this subfamily. The biogeographical implications of the presence of elephantines in the late Miocene of East Africa, and their absence from the post-Messinian of Libya, are discussed elsewhere[8].

At least seven cercopithecid genera are recognized in the Middle Awash. Those accorded the most attention, species close to the modern *Cercopithecus* and *Colobus* monkeys, are exceptionally well-represented in the Andalee Member[10]. The excellent preservation and abundance of monkeys of these forms and age are unknown elsewhere. *Theropithecus* (*Simopithecus*) is also abundantly represented, in almost all known forms of *T. oswaldi*[56] (including, as a subspecies, *T. darti*). These range from a primitive form from Wee-ee (Kalaloo beds?), similar to material known throughout the Hadar Formation, to derived forms from the Wehaietu Formation that recall *T. o. mariae* and *T. o. leakeyi* from East Africa[56].

The recognition of extensive, highly fossiliferous strata antedating the Hadar Formation raises the possibility of documenting the earlier stages of hominid evolution. The hominid remains from the Hadar Formation have been vigorously touted as representatives of a single, thoroughly plesiomorphous hominid species ancestral to all known later forms[37]. This view is not unchallenged, others (see, for example, ref. 57) seeing representatives of two lineages in the collection. In any case, there is evidence that bipedal hominids were present earlier than 4 Myr at Kanapoi[58], and a hominid-like hominoid of uncertain affinities and unknown locomotor type is known from Lothagam-1[59]. It is hoped that the Adu-Asa Formation, which contains abundant fauna and apparently overlaps both Lothagam-1 and Kanapoi, will in time yield hominid specimens sufficiently complete to be assignable to an unambiguous position within the hominid clade, and thus to throw light on the timing and circumstances of the initial radiation of the family.

Like other East African sites, the Middle Awash sees the first appearance of clearly recognizable human artefacts in the late Pliocene (Matabaietu and upper Hadar Formations). When analysed more fully, the many occurrences of artefacts together with the remains of animals in this and the Wehaietu Formation will permit the testing of hypotheses about the relative importance of hunting, scavenging and fortuitous association in producing such archaeological sites in the Plio–Pleistocene. The hominid skull recovered from the base of the Wehaietu Formation at Bodo[11] not only provides critical evidence on archaic *Homo sapiens*; it also provides an unequivocal relationship between the morphological grade of tool-maker with a specific 'grade' in Acheulian technology. Overlying Acheulian tool-bearing units may yield other hominids of potentially more derived forms. Most significantly, the presence of ample tuffs throughout the Acheulian sequences allows for construction of a chronometric framework for both changing technologies and technicians, in what may well be the single most extensive Acheulian deposits described.

The diversified lithic 'Sangoan' industry at Andalee may document that transitional period between the longstanding conservatism of the Acheulian and the relative cultural diversity that characterizes the late Pleistocene[7]. The Andalee industry and its predominantly smaller fauna stand in marked contrast to the association of large tools and large game animals found in the Acheulian sites. Kalb *et al.*[9] speculate this may reflect adjustments to faunal turnover and changing man–land relationships following a prolonged arid period at the end of the Middle Pleistocene. Further studies at Andalee will elucidate this question, as will work at nearby Issie.

Overall, the succession of Acheulian, Sangoan and MSA industries in the Wehaietu Formation may provide a reasonable picture of man–land relationships during the middle and late Pleistocene during such crucial events as the first appearance of artificial fire in the region, the Acheulian–Sangoan transition, and thence to the MSA and LSA, and the appearance of modern humankind.

Conclusions

The Middle Awash Valley contains a largely complete record of mammalian evolution spanning at minimum the past 5–6 Myr. This record is contained within a stratigraphical sequence >1 km thick, making it one of the most extensive fossil sequences in the African Neogene. Evidence of hominid habitation, in the form of hominid fossils or artefacts, is found here in >0.5 km of beds, extending over ~4 Myr, from the lower levels of the Hadar Formation[37] to the Matabaietu Formation, through the Wehaietu Formation and the Holocene beds. The Middle Awash contains one of the most continuous records of hominid habitation in the Old World. Likewise, the stone tool occurrences extending throughout over 300 m of the Awash sequence, encompassing of the order of 2–2.5 Myr, from the upper Hadar Formation and the Matabaietu Formation to the Recent, documents one of the most continuous records of human cultural change known.

The present work and that in our previous paper, should lay a firm foundation for a coherent and orderly programme of research in the Middle Awash in the years to come.

Protection against foot-and-mouth disease by immunization with a chemically synthesized peptide predicted from the viral nucleotide sequence

James L. Bittle, Richard A. Houghten, Hannah Alexander, Thomas M. Shinnick, J. Gregor Sutcliffe & Richard A. Lerner

Chemically synthesized peptides corresponding to two different regions of the VP1 polypeptide of foot-and-mouth disease virus (FMDV) produced high levels of serotype-specific virus neutralizing antibody in cattle, guinea pigs and rabbits. A single inoculation of one of these peptides protected guinea pigs against subsequent challenge with the virulent virus.

FOR at least four centuries foot-and-mouth disease has been one of the world's major animal plagues[1]. The virus affects both domestic and wild ruminants and swine. Its ease of dissemination, coupled with the loss of productivity of the animals following infection, usually estimated at 25%, make it a disease of major concern. The problem is worldwide as the disease is present in every continent except Australia and North America. The disease is controlled by slaughter in those countries where it does not normally occur but vaccination is used where it is endemic. The extent of the problem is such that over 1,000 million doses of vaccine are used each year but, although vaccines have been available for the past 40 years, the disease is still widespread. The vaccines are produced by inactivation of virus harvests produced in cultures of baby hamster kidney cells or in bovine tongue epithelium fragments. Although these vaccines are generally effective, there are certain drawbacks to their use. For example, several strains of the virus cannot be grown to a titre high enough to provide sufficient antigenic mass for effective vaccination. In addition, the virus particle is very unstable, particularly below *p*H 7, so it is necessary to store vaccines under refrigeration to retain their potency. This is clearly a major limitation, particularly in tropical climates. The recent association of outbreaks of the disease in Europe with improperly inactivated virus[2] illustrates another disadvantage of this type of vaccine, particularly in those regions of the world where the disease has been virtually eradicated. These disadvantages have prompted continuing studies on the structural features of the virus particle that are necessary for immunogenic activity with a view to developing alternative vaccines.

The virus, which belongs to the aphthovirus genus of the family Picornaviridae, contains one molecule of infectious single-stranded RNA of molecular weight (M_r) $\sim 2.6 \times 10^6$ and 60 copies of each of four polypeptides VP1–VP4 (ref 3). An important antigenic role for VP1 is indicated by the fact that treatment of the virus particle with trypsin results in the cleavage of only this polypeptide, with a concomitant decrease in infectivity and, depending on the virus strain, a loss of immunizing activity[4]. Indeed, VP1 isolated from virus particles has some, albeit very low, immunizing activity[5–8], whereas the other three viral polypeptides have no such activity. Based on this observa-

Table 1 Antibody response of rabbits to different peptides of VP1 of FMDV, type 0, strain Kaufbeuren

Rabbit no.	Peptide	Anti-peptide antibody titre	Neutralization index ($\log_{10}$)*
1	9–24	80–160	≤ 0.3
2	9–24	40–80	≤ 0.3
3	17–32	80–160	≤ 0.5
4	17–32	20–40	≤ 0.9
5	25–41	40–80	≤ 0.5
6	25–41	640–1280	≤ 0.9
7	1–41	320–640	≤ 0.9
8	1–41	320–640	≤ 0.7
9	141–160	320–640	≥ 3.9
10	141–160	320–640	≥ 3.7
11	151–160	80–160	2.9
12	151–160	160–320	1.1
13	200–213	>1280	3.5
14	200–213	160–320	3.1

In the second column, numbers refer to the amino acid, starting at the amino-terminus. Rabbits were immunized with peptide-coupled KLH inoculating 200 μg in complete Freund's adjuvant (1:2) s.c. in the footpad on day 0; 200 μg in incomplete Freund's adjuvant s.c. on day 14; 200 μg with 4 mg of aluminium hydroxide intraperitoneally (i.p.) on day 21 and day 50 and were then bled on day 57. The enzyme-linked immunosorbent assay (ELISA) was used to test all antisera for their ability to react with the peptide used for immunization. Antibody was bound to antigen immobilized on polystyrene plates and the antigen–antibody complex was detected using an enzyme-labelled goat anti-rabbit IgG. Five pmol of antigen in 0.1% bovine serum albumin (BSA) phosphate-buffered saline (PBS) were added to each well of a 96-well microtitre plate and dried overnight at 37 °C. The dried antigen was then fixed to the plates with 50 μl per well of methanol for 5 min at room temperature. Before adding the antibodies, the plates were coated for 4 h with 3% BSA/PBS to block nonspecific adsorption of antibodies to the plate. Twofold serial dilutions of each antiserum were prepared in minimal essential medium containing 10% fetal calf serum, 25 μl of the serum dilution were added per well and the plates were incubated overnight at room temperature. Unbound antibody was then washed off with water. The antigen–antibody complex was reacted with 25 μl per well of 1:100 dilution of goat anti-rabbit IgG coupled to glucose oxidase. Excess goat anti-rabbit antibody was washed off with water and the reaction was developed by adding 50 μl per well of developing solution [25 ml 0.1 M Na-phosphate buffer, *p*H 6.0, 3 ml 20% glucose, 200 μl 0.1% horseradish peroxidase, 200 μl of chromogen (2,2′-amino-di-[3-ethylbenzthiazolin-sulphonate]) at 20 mg ml^{-1} in Na-phosphate buffer, *p*H 6.0]. The plates were read in a Titertek Multiskan at 414 nm, and the values presented are the reciprocal of the serum dilution binding to 50% of 5 pmol of antigen.

* Equal volumes of virus dilutions and undiluted sera were inoculated i.p. into suckling mice. The values give the difference between the titre of the virus plus normal serum and the virus plus antiserum.

Fig. 1 The 213-amino acid sequence of VP1 as translated by Kurz *et al.*[13] from the nucleic acid sequence. Regions of the protein chosen for synthesis are indicated by bold underlining. C or Y at the end of such a line indicates the addition of cysteine or tyrosine not found in the primary sequence. Peptides were synthesized by the solid phase method[17–19] using a Beckman Model 990B peptide synthesizer. The initial amino acid resin was prepared by esterification of Boc-(MeoBzl)-Cys-OH (2.0 g of the anhydrous caesium salt. 4.3 mequiv) to chloromethylated resin (polystyrene–1% divinylbenzene, bio-beads S.X -1, 200–400 mesh, 0 70 mmol g^{-1}) in 25 ml anhydrous dimethylformamide (DMF) by stirring for 24 h at 50 °C. A threefold excess of caesium salt over active chloride polymer was found to give almost complete substitution. Substitution was determined to be 0.55 mequiv g^{-1} by the picric acid test and amino acid analysis, and 0.53 mequiv g^{-1} following HCl-propionic acid hydrolysis. For each synthesis, 1 0 g (0.53 mequiv) of Boc-(MeoBzl)-Cys resin was used The following side-chain protecting groups were used. *O*-Br-Z for lysine and tyrosine; *O*-benzyl for threonine, serine, aspartic acid and glutamic acid; tosyl for arginine; *N*-formyl for tryptophan; and *N*-dinitrophenyl for histidine. Protected amino acids (from Vega Biochemicals or Peninsula Laboratories) were recrystallized from the appropriate solvent to give single spots on TLC (chloroform/acetic acid = 15:1 or chlorofrom/methanol = 10:1) All couplings were carried out using a 10-fold excess of Boc-AA-OH. For asparagine and glutamine, an equimolar amount of *N*-hydroxy benzotriazole was added to the protected amino acid and dimethyl formamide was used as the solvent. All coupling reactions were ≥99% complete by the picric acid test. The removal of dinitrophenyl from histidine-containing peptides was accomplished with *N*-methyl mercaptoacetamide[20] in DMF by mixing with the resin-bound peptide for 15 min. Removal was >95%. The protected peptide polymers (500 mg to 2.5 g, 0 12–0 60 mequiv) were treated with twice their weight of anisole and with 40 times their volume (relative to weight) of anhydrous HF at 4 °C for 1 h. For peptides containing glutamic acid, 5% v/v pyridine was added to the HF to prevent anisylation. After evaporating the HF with a stream of N_2, the red residue was mixed with anhydrous ether (50×, w/v) and stirred vigorously for 15 min; after repeating the ether extraction three times, the white residue was filtered and dried *in vacuo*. This dried resin–peptide mixture was generally extracted with 5% HOAc, lyophilized and amino acid analysis performed (approximately 90% removal of the peptide from the resin was accomplished in this manner). For peptides containing tryptophan, the *N*-formyl protecting group was removed from the peptide by treatment for 1.5 min at *p*H 11.5 (NaOH) in the presence of hydrazine. If the amino acid analysis was acceptable (±5% of theory), the peptides prepared in the above manner were used directly, if not, they were purified to the desired extent by CM-cellulose chromatography, partition chromatography, or HPLC as needed. Yields ranged from 20–60% depending on the given peptide, and the purity needed The peptides were coupled to a protein carrier, KLH, through the cysteine of the peptide, using *N*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS) as a coupling agent, as described by Liu *et al.*[21].

tion, workers in Europe and the USA[9–11] have investigated the possibility of producing the protein by recombinant DNA technology, and Kleid *et al.*[11] have produced by this means 1–2 × 10^6 copies of VP1 per *Escherichia coli* cell. However, the expressed protein appears to be no more active weight for weight than VP1 produced from virus particles and it is clear that much remains to be learned about the structural features necessary for effective immunization before VP1 can be considered a realistic alternative to killed virus particles.

Application of recombinant DNA technology has also allowed nucleotide sequences of the virus genome to be determined, from which the primary amino acid sequence of VP1 can be deduced. Sequences are now available for two strains of serotype A[11,12] and one of type O[13]. In addition, Strohmaier and his colleagues[14] have provided evidence, by measuring the immunogenic activity of enzymatically or chemically derived fragments of VP1 of the type 0 strain, that sites eliciting neutralizing antibody are located in the carboxy-terminal half of the molecule. We have chemically synthesized peptides corresponding to several regions of VP1 of this strain of virus and report here that some of these induce neutralizing and protective antibodies against the disease.

Chemically synthesized peptides induce neutralizing antibodies in rabbits

Previous studies[14] indicated that the carboxy-terminal region was important in inducing neutralizing antibody. In addition, nucleic acid sequencing of the two strains of type A[11,12] and one of type 0[13] demonstrated that there was considerable variability between positions 130–160 and 190–213. We reasoned that this variability was due to the availability of these regions for interaction with neutralizing antibody and their consequent subjection to high selective pressure. To study the molecule further, we also selected a series of N-terminal peptides for synthesis. Seven peptides from VP1 of type 0 virus (strain Kaufbeuren), corresponding to four regions near the amino-terminus (1–41), one at the carboxy-terminus (200–213) and two near the centre of the molecule (141–160 and 151–160) were synthesized, coupled to keyhole limpet haemocyanin (KLH) and inoculated into rabbits (see Fig. 1). The KLH-coupled peptides elicited anti-peptide antibody titres as assayed by ELISA (Table 1). However, a virus neutralizing antibody response was elicited only by the peptides in the middle region and at the carboxy-terminus.

The serotype specificity of the antibodies produced in the rabbits by the peptides spanning regions 141–160 and 200–213 was determined in neutralization tests using the homologous virus and viruses of types A and C. Although there was some cross-neutralization, the level was considerably lower than that of the homotypic reaction (Table 2). These results show that the serotype specificity of the sera produced by inoculation of the synthetic peptides mimicks that found with sera against whole virus. The cross-neutralization may reflect the limited sequence homology among the different serotypes.

Guinea pigs immunized with synthetic peptides are protected against foot-and-mouth disease

Having established that peptides 141–160 and 200–213 produced high levels of neutralizing antibodies on multiple inoculation into rabbits, we tested the effectiveness of a single inoculation of the antigens in producing neutralizing antibodies in guinea pigs and in providing protection against challenge. Guinea pigs were inoculated subcutaneously (s.c.) with 20 or 200 μg of either of the two peptide conjugates, mixed with

Table 2 Serotype specificity of the anti-peptide antibodies

Antibody to peptide region:	Neutralization index ($\log_{10}$)* against		
	0 Kaufbeuren	C Indaial	A-61
141–160 (rabbit 9)	4.3	−0.1	1.1
141–160 (rabbit 10)	≥6.3	1.9	2.3
200–213 (rabbit 13)	2.9	−0.1	1.5
200–213 (rabbit 14)	3.3	0.3	1.5

C Indaial belongs to serotype C, subtype 3; A-61 belongs to serotype A, subtype 10.

* See Table 1 legend.

Freund's complete adjuvant or aluminium hydroxide gel. Parallel groups of animals were inoculated with either 1 or 10 μg of purified inactivated virus particles mixed with either of the same two adjuvants. After 35 days, the animals were bled by heart puncture to determine the level of neutralizing antibody and then challenged by inoculating one hind footpad with 10^4 ID_{50} (50% infectious dose) of the homologous virus which had been passaged once in guinea pigs. The results, summarized in Table 3, demonstrate the effectiveness of peptide 141–160 in producing neutralizing antibody and protecting the animals against infection. As little as 200 μg provided complete protection and even 20 μg provided substantial protection, in view of the severity of the challenge. There was good correlation between the level of neutralizing antibody and the response to challenge. Those animals whose sera had a neutralizing index of ~1.5 or greater were protected.

In contrast, inoculation of guinea pigs with a similar amount of VP1, prepared by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) gave a much lower neutralizing antibody response. We have observed this for several different preparations of VP1 from viruses of types 0 and A.

Biochemical characterization of the virus components reacting with the anti-peptide sera

The rather surprisingly superior neutralizing antibody response of the animals to inoculation with the synthetic peptides, compared with that observed in studies using VP1, prompted us to explore the basis for this difference. As only the antisera to peptides 141–160 and 200–213 had neutralizing activity, we confined our experiments to these and we have characterized the reactivities of these novel reagents in a variety of assays commonly used in this virus system. First, the antisera were tested for their ability to precipitate purified ^{35}S-methionine-labelled virus antigens (Table 4). Intact 146S virus particles were precipitated by (1) the anti-peptide sera, (2) a rabbit antiserum prepared against purified VP1, (3) convalescent guinea pig serum and (4) guinea pig serum prepared against 146S particles. With the exception of the serum against the 146S particles, the same antisera also precipitated the 12S virus protein subunit, which is a pentamer of VP1–3, produced by heating 146S particles to 60°C. The lack of reaction between antisera to 146S particles and the 12S subunit has been described previously[15]. Disruption of the 146S particle into its constituent polypeptides by treatment with 8M urea at 37 °C, followed by dilution to reduce the urea concentration, led to a loss of reactivity with the anti-146S serum and a considerable reduction in its reaction with the convalescent serum. However, there was less reduction with three of the four anti-peptide sera. The anti-VP1 serum precipitated the denatured protein efficiently.

Table 3 Protection of guinea pigs against challenge with FMDV by inoculation with inactivated virus particles, VP1 or synthetic peptides 141–160 and 200–213

Antigen	Dose (μg)	Adjuvant	Neutralization index ($\log_{10}$)*	No. protected/ No. challenged
Virus	1	$Al(OH)_3$	2.7(1.1–2.3)	1/4
	10	$Al(OH)_3$	≤4.9(3.4–≤4.5)	2/2
	1	Freund's	2.5(1.3–2.9)	2/2
	10	Freund's	≤5.3(≤4.5)	4/4
VP1	20	$Al(OH)_3$	0.5(0.1–0.9)	ND
141–160	20	$Al(OH)_3$	2.1(0.9–2.7)	3/4
	200	$Al(OH)_3$	2.7(1.7–≤3.7)	3/3
	20	Freund's	2.1(0.1–2.5)	1/4
	200	Freund's	≤3.3(1.5–≤3.3)	4/4
200–213	20	$Al(OH)_3$	1.1(ND)	1/3
	200	$Al(OH)_3$	0.7(ND)	2/4
	20	Freund's	1.1(ND)	0/4
	200	Freund's	0.5(ND)	0/4

* Neutralizing activity of pooled serum from eight animals. Values in parentheses give the range of activity in the individual animals that were challenged. ND, not done.

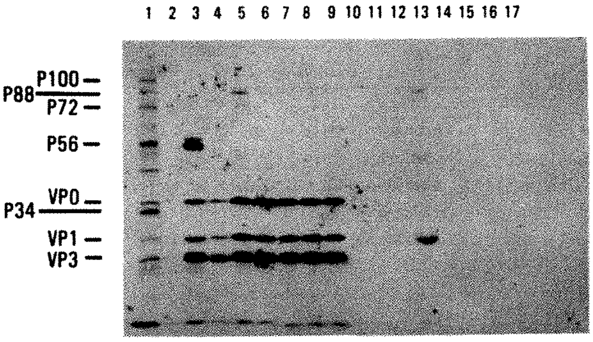

Fig. 2 Comparison of immune precipitation of viral proteins by different antisera. FMDV-infected BHK 21 cells were labelled with ^{35}S-methionine from 2.5 to 3 h post-infection, when host cell protein synthesis was almost completely halted. The cells were then lysed by treatment with 1 ml of 1% NP-40, 0.5% DOC in 0.15 M NaCl, 50 mM Tris-HCl, *p*H 7.5 and the nuclei pelleted in a microfuge for 5 min. Aliquots (20 μl) of the supernatant were diluted with 1 ml of NETS (0.15 M NaCl, 5 mM EDTA, 50 mM Tris-HCl, *p*H 7.5 and 0.5% NP40) immediately, or after adding SDS to 1% and heating at 100 °C for 2 min. The appropriate antiserum (30 μl) was added to each sample and complexes allowed to form at 4°C overnight. Washed, inactivated *Staphylococcus aureus* ghosts (Pansorbin) were then added to adsorb IgG molecules and separated by centrifuging for 5 min in a microfuge. The pellets were washed twice with NETS and the adsorbed IgG and complexed antigens eluted by suspending the pellets in Laemmli disruption buffer[22]. The proteins were denatured by heating at 100 °C for 2 min and separated on an 11% Laemmli gel[22]. The gels were prepared for fluorography[23] and exposed to X-ray film. Lane 1, total cell extract; lanes 2–9, immune precipitates of undenatured extracts; lanes 10–17, immune precipitates of SDS-denatured extracts. Lanes 2 and 10, control rabbit serum; lanes 3 and 11, convalescent guinea pig antiserum; lanes 4 and 12, guinea pig antiserum to 146S particles; lanes 5 and 13, rabbit antiserum to VP1; lanes 6 and 14, antiserum 9 to peptide 141–160; lanes 7 and 15, antiserum 10 to peptide 141–160; lanes 8 and 16, antiserum 13 to peptide 200–213; lanes 9 and 17, antiserum 14 to peptide 200–213.

The same antisera were then tested for their ability to precipitate the virus-specfic antigens in infected BHK 21 cells. The antigens were extracted in their native state by disrupting the cells with deoxycholate (DOC) and Nonidet P-40 (NP40)[16] and used either directly or after denaturation by heating at 100 °C in the presence of 1% SDS. The immunoprecipitated proteins were separated by PAGE (Fig. 2); all the antisera precipitated both the virus structural proteins and their precursor, P88 (lanes 3–9). The convalescent antiserum also precipitated some of the non-structural polypeptides. As the structural proteins are present as complexes when extracted from cells in these conditions, antisera reactive with VP1 also precipitate the other structural polypeptides.

After denaturation of the proteins with SDS, only the rabbit anti-VP1 serum precipitated VP1 and the structural protein precursor P88 (Fig. 2, lane 13); VP1 was precipitated neither by the control rabbit serum (lane 10), by convalescent serum (lane 11) nor by the anti-146S serum (lane 12). The antisera against peptides 141–160 (lanes 14, 15) and 200–213 (lanes 16, 17) precipitated very little of the SDS-denatured antigens; a very faint VP1 band could be seen in the 200–213 precipitates on the original autoradiograph.

The reactivity of the various antisera for denatured molecules was further examined by the Western blotting technique, whereby the proteins from purified denatured virus particles were separated by SDS-PAGE, transferred to nitrocellulose, probed with antiserum and the reaction visualized by autoradiography after binding ^{125}I-labelled protein A. The results (Fig. 3) again show a lack of reaction between VP1 and the convalescent and anti-146S sera (lanes 2 and 3) and a strong reaction with anti-VP1 serum (lane 4). Reaction between the 200–213 antisera and VP1 (lanes 7, 8) was more obvious than in the immunoprecipitation experiment (Fig. 2); only a weak reaction with the two anti-141–160 sera (lanes 5, 6) was seen.

Taken together, these data indicate that the anti-peptide sera react with the protein species containing the appropriate sequence, including precursor molecules, and that they resemble anti-viral anti-sera in reacting well with native components. Because of their propensity to bind to native VP1, these sera also precipitate other protein species which, in non-denaturing conditions, are bound to the primary target by virtue of the protein–protein interactions important in the structure of this virus. On the other hand, it is clear that the activity of the anti-VP1 serum is directed primarily against denatured protein, an observation easily understandable in view of the fact that this serum was prepared against SDS-denatured protein. VP1 isolated by other means has been an equally poor antigen for generating an anti-viral response (D.J.R. and F.B., unpublished work).

Discussion

Table 4 Precipitating activity of different antisera against the 146S virus particle, 12S subunit and viral polypeptides

		Amount of antigen precipitated (counts per 20 min)		
Serum	Animal	146S particle	12S subunit	Viral polypeptides
Normal	Rabbit	667	616	637
Convalescent	Guinea pig	2,692	1,833	742
146S particle	Guinea pig	2,889	668	646
VP1	Rabbit	3,231	2,457	1,553
141–160	Rabbit 9	3,123	2,212	774
141–160	Rabbit 10	3,174	2,312	1,047
200–213	Rabbit 13	3,434	2,259	1,070
200–213	Rabbit 14	3,215	2,266	1,127

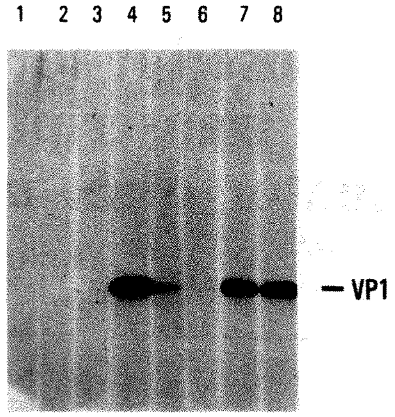

Fig. 3 Comparison of the reaction of different antisera with separated viral polypeptides. Purified FMDV 146S particles were denatured with Laemmli disruption buffer[22] at 100 °C for 2 min and the proteins separated on a 10% polyacrylamide gel slab. The proteins were electrophoretically transferred to a nitrocellulose sheet which was then cut into strips. The strips were immersed in a solution of 10 mg ml^{-1} haemoglobin containing the different antisera. After thorough washing, the strips were immersed in a solution of ^{125}I-labelled *S. aureus* protein A. The washed, dried strips were then exposed to X-ray film to visualize the binding of protein A to IgG molecules immobilized on the strips. Lane 1, control rabbit serum; lane 2 convalescent guinea pig antiserum; lane 3, guinea pig antiserum to the 146S particle; lane 4, rabbit antiserum to VP1; lanes 5 and 6, rabbit antisera 9 and 10 to peptide 141–160; lanes 7 and 8, rabbit antisera 13 and 14 to peptide 201–213.

Our results show that a single inoculation of the synthetic peptide 141–160 elicits sufficient neutralizing antibody to protect guinea pigs against subsequent challenge with FMDV. Although we have not yet accumulated sufficient data to allow a precise comparison, the results obtained so far indicate that, on an equal weight basis, a single peptide has from one to as much as 10 per cent of the activity of the inactivated virus particle. Furthermore, the neutralizing antibody titre elicited by the peptide is several orders of magnitude greater than the best results obtained by immunization with the capsid protein VP1, irrespective of whether this is produced by disruption of virus particles[5–8] or by expression in *E. coli* cells[11]. Indeed, in several of our own experiments (for example, see Table 3) and in other studies[5–8], the level of neutralizing antibody response to one inoculation of the capsid protein was negligible. The reason for this difference may be that the antibody induced by the synthetic peptide is more closely related qualitatively to that induced by virus particles than to that induced by VP1. It is possible that the separated VP1 does not fold properly when deprived of the scaffolding provided by the other capsid proteins. Thus the immunodominant site presented to the immune system by free VP1 may be largely irrelevant to neutralization. In contrast, a small free peptide may be able to adopt a conformation approximating that which it assumes in the virus particle, a situation that is unlikely when it is constrained by the neighbouring amino acids in an improperly folded VP1.

One clear advantage of the synthetic 141–160 peptide is its activity in eliciting a protective antibody response after a single inoculation. This good response to a single inoculation is important, because successful immunization against foot-and-mouth disease in the field depends on the vaccines being sufficiently active to produce a protective response with one inoculation. Indeed, preliminary work in cattle and pigs shows that the synthetic peptide 141–160 can elicit an antibody response sufficient to protect these species against the disease. Thus the prospects for a totally synthetic vaccine against foot-and-mouth disease are encouraging.

We thank David Morrell for the Western blot experiment and Janet Haresnape for the anti-VP1 serum.

Note added in proof: Since the submission of this article, we have obtained evidence that synthetic peptides corresponding to amino acids 141–160 of the VP1 of two subtypes of serotype A of FMDV (subtype 10, strain 61 and subtype 12, strain 119) also elicit the production in rabbits of levels of neutralizing antibody similar to those described here.

Transcript secondary structures regulate transcription termination at the attenuator of *S. marcescens* tryptophan operon

I. Stroynowski* & C. Yanofsky

Department of Biological Sciences, Stanford University, Stanford, California 94305, USA

We have analysed the regulatory behaviour of deletion mutants lacking different segments of the leader region of the tryptophan operon of Serratia marcescens. *Our results support the model in which a particular RNA structure, the terminator, is recognized during transcription as a transcription termination signal, and an alternative RNA structure, the anti-terminator, prevents formation of the terminator. It appears that the role of translation, ribosome stalling and shifts between alternative RNA secondary structures, is simply to regulate formation of the terminator.*

SEVERAL bacterial operons encoding amino acid biosynthetic enzymes are regulated by attenuation (for reviews see refs 1–3). This regulatory mechanism involves controlled transciption termination at a site, the attenuator, located in the leader region, the segment of the operon between the transcription start site and the first structural gene. Comparison of the sequences of the leader regions of the six-amino acid biosynthetic operons known to be regulated by attenuation[4–7] reveals considerable similarities. Each operon has a potential peptide-coding region in the leader transcript which, if used, would specify a small peptide rich in the regulatory amino acid. Immediately beyond, there is a site of transcription termination, an attenuator. This site consists of an A + T-rich sequence preceded by a G + C-rich sequence exhibiting dyad symmetry. The segment of the transcript corresponding to the G + C-rich region in each operon can potentially form a stable hydrogen-bonded stem and loop structure. Transcription termination at the attenuator of each of these operons is controlled by the extent of charging of appropriate transfer RNAs with the regulatory amino acid, implicating leader peptide synthesis in the regulation of termination.

A model attempting to explain attenuation was proposed by Lee and Yanofsky[4] for the *trp* (tryptophan) operon of *Escherichia coli*. It was suggested that a G + C-rich secondary structure forms in the transcript just before RNA synthesis stops and serves as the recognition signal for transcription termination at the attenuator. An alternative secondary structure in the transcript was also predicted. If this structure, located in the earlier segment of the leader transcript, formed, it could prevent formation of the presumed transcription termination signal. It was hypothesized that this alternative secondary structure would eliminate transcription termination at the attenuator and thereby increase expression of the operon. The switch between the alternative RNA secondary structures was proposed to be regulated by ribosome movement along the transcript during translation of the coding region for the leader peptide. Specifically, ribosome stalling at the tandem Trp codons of the transcript—a consequence of the unavailability of charged tRNA^{Trp}—was thought to mask a critical segment of the transcript, thus favouring formation of the RNA stem and loop mutually exclusive with the formation of the termination secondary structure. This interpretation is consistent with the results of subsequent studies on attenuation performed with the *trp* operons of *E. coli* and other enteric bacteria[4–7]. The model has been applied to other amino acid biosynthetic operons; it has been used to explain attenuation in the *phe*[8], *his*[9], *thr*[10], *leu*[11] and *ilv*[12,13] operons.

Many features of the proposed model have not been verified by studies with any of the operons mentioned. We report here the results of experiments designed to test the fundamental hypothesis that alternative RNA secondary structures are involved in the regulation of transcription termination at the *trp* attenuator.

A model for attenuation in the *trp* operon of *S. marcescens*

Mutational and physiological studies with *Serratia marcescens* indicate that the *trp* genes of this enterobacterium are coordinately regulated in response to changes in tryptophan concentration[14–16]. The regulatory region of the *S. marcescens trp* operon is organized identically to those of *Escherichia coli* and *Salmonella typhimurium*[17]. There is a promoter–operator used to regulate transcription initiation and a leader region within which transcription termination is controlled.

Figure 1 gives the alternative RNA secondary structures of *S. marcescens* analogous to those of the *E. coli* leader transcript, and Fig. 1*a* shows the secondary structures that could be predicted to form *in vitro*. On the basis of studies with the *trp* operon of *E. coli*, the *in vivo* studies described here, and the results of *in vitro* transcription experiments to be presented elsewhere, we believe that the stem and loop structure labelled 3:4 in the figures is the structure recognized by the transcribing polymerase as a transcription termination signal; for example, deletion mutants that can only form structure 3:4 efficiently terminate transcription at the attenuator *in vivo* and *in vitro*. In view of these findings, structure 3:4 will henceforth be designated the 'terminator'[11]. When cells are starved of tryptophan, the ribosome translating the peptide-coding region is believed to stall over either of the adjacent Trp codons, thereby masking transcript segments A1, 1B and 2B. In these conditions, secondary structure 2A:3 could form before the synthesis of segment 4, and thereby preclude formation of the terminator. Substantial *in vivo* and *in vitro* evidence indicates that structure 2A:3 has an important role in preventing termination. We shall designate a structure such as 2A:3 in Fig. 1*b* as an anti-terminator. The stalled ribosomes shown in Fig. 1*b* are centred over the His and Arg codons of the peptide-coding region. Ribosomes stalled at these positions would block pairing of 1A with 2A, and 1B with 2B, but would not interfere with pairing of 2A with 3. These schematic representations are based on the findings in Table 1 showing that starvation for His, Trp or Arg relieves transcription termination at the *trp* attenuator of *S. marcescens*. Starvation for proline, a residue not present in the leader peptide, has no effect. These observations support the conclusion derived from comparable studies performed with *E. coli*[6] and suggest that attenuation is regulated through ribo-

Fig. 1 . Secondary structure alternatives in the *S. marcescens trp* leader transcript. Numbering is from the presumed 5′ nucleotide of the transcript. The likely leader peptide initiation and termination codons are enclosed in boxes and the predicted amino acid sequence of the transcript is as reported[17] except for an additional A residue at position 150 The numbered RNA segments are those thought to participate in the various secondary structures that either cause or prevent transcription termination at the attenuator. The structures in *a* are predicted to form *in vitro*; hairpin loop 3:4 is believed to be the signal responsible for transcription termination. When the transcript is translated *in vivo* coincident with transcription of the *trp* leader region, structure 3·4 is thought to form and cause transcription termination. *b* Shows an alternative secondary structure. This structure, 2A.3, is believed to form in cells starved of His, Gly, Trp or Arg because the translating ribosome (schematically represented as dashed bullets stalled over His and Arg codons) stalls in the critical region of the transcript. Formation of structure 2A·3 prevents formation of structure 3·4, thereby preventing transcription termination. The various structures have the following calculated free energies of formation[19]· 1:2, $\Delta G = -4$ kcal mol^{-1} (see text for discussion); 2·3, $\Delta G = -19.6$ kcal mol^{-1}, 3.4, $\Delta G = -21.6$ kcal mol^{-1}. The hypothetical structure formed by pairing of nucleotides 3–19 with 23–27 has a theoretical $\Delta G = -1.8$ kcal mol^{-1}. To simplify discussion of potential secondary structures we have assumed that this structure forms We know of no function for such a structure

some stalling over a crucial segment of the transcript and not by the tryptophan deficiency *per se*.

If the role of the ribosome is simply to mask appropriate segments of the *trp* transcript, we could simulate such masking by deleting the corresponding segment of the transcript. Accordingly, we produced a set of overlapping deletions having both termini within the leader region. We selected those deletions that also removed the leader peptide ribosome-binding site and translation start codon to avoid the complication of translation. We describe here the *in vivo* analysis of the effects of these deletions on attenuation.

Analysis of deletion mutants lacking segments of the *trp* leader region of *S. marcescens*

Deletions around the *Hpa*I site, nucleotides 32–37, in the *trp* leader region were produced *in vitro* by exonuclease digestion, as described in the accompanying paper[18]. Each deletion mutant was characterized by DNA sequence analysis to determine the deletion junction. The leader regions containing deletions were then introduced into the chromosome in single copy form for operon expression studies. The recipient for these studies was an *E. coli* strain that lacked the *trp* repressor and had a deletion of *trpE* (*trpR* Δ *trpLE1413*). This deletion removes the *E. coli trp* attenuator and *trpE*, resulting in the production of sufficiently high levels of the *trpD* protein of *E. coli* to activate a broad range of levels of *S. marcescens trpE* protein. Cultures were either grown with excess tryptophan or starved of this amino acid. As the translation start codon of the leader transcript was deleted in all the deletions analysed, the +Trp values are most relevant to considerations of operon expression.

Figure 2*a* summarizes expression data for four deletions that remove the leader translation start codon. With the exception of deletion 221, operon expression, and presumably transcription readthrough, is reduced to 8–18% of the value obtained with the wild-type leader region. As documented in the accompanying paper[18], deletions that prevent translation of the peptide-coding region cause increased termination, or superattenuation. Presumably, in such strains secondary structure 1A–1B:2A–2B forms and prevents pairing of 2A with 3. Thus, 3:4, the terminator, forms at high frequency. In this explanation it is assumed that when the coding region is translated in wild-type, structure 2A:3, the anti-terminator, forms occasionally, leading to a moderate level of transcription readthrough. Deletion mutant 221 requires additional explanation. The sequence created by the deletion in this strain, CGGCC.AACAC (nucleotides 16–18 fused to nucleotides 56–58), is complementary to the 1A–1B junction (nucleotides 78–83, Fig. 2*a*) and conceivably could pair with this segment and thereby reduce the frequency of 1A–1B pairing with 2A–2B. Free 2A–2B would thus be available to generate the anti-terminator. Mutant 307, which differs from 221 by only one base pair (C is substitued by G at position 18), has fourfold lower expression. In agreement with this result, it can be calculated that this C→G substitution considerably reduces the theoretical estimate of the free energy of the potential secondary structure (from $\Delta G = -5.6$ to $\Delta G = +1.6$ kcal mol^{-1}).

The importance of segments 1A and 1B in the regulation of transcription termination is evident from analyses of deletions having endpoints in these segments (Fig. 2*b*). In general, as more of segment 1A–1B is removed, the level of observed *trpE* expression increases until it reaches values of ~400%, reflecting the absence of termination at the attenuator. Mutant 206 is an

Table 1 The effect of starvation for various amino acids on readthrough transcription in the *S. marcescens trp* operon

Growth conditions	% Of pulse-labelled RNA annealed to *S marcescens trpE* DNA	Relative *trpE* mRNA levels
Non-starved	0.13	(100%)
Trp-starved	0.62	476
Arg-starved	0.53	410
His-starved	0.46	353
Pro-starved	0.15	115

The numbers in the last column indicate the average structural gene *trpE* mRNA level expressed by λSm4 derivatives in *E. coli* starved for the particular amino acid, relative to the value obtained with a non-starved culture (100%). The results are averaged from six experiments. The error of the measurement is 20% of the number given. The non-starved λSm4 lysogen (*E coli* background, LS993 *trpR* Δ*trp ED24 argE his pro ilv*) was grown in minimal medium containing 0.05% casein hydrolysate, 0.2% glucose and 50 μg ml^{-1} of required amino acids. Samples of this culture were filtered, washed and starved of individual amino acids for 5 min before being pulse-labelled for 30 s at 30 °C with ^{3}H-uridine. The labelled RNA was hybridized in duplicate to plasmid pITS 9, which carries *S. marcescens trpE*, and the vector plasmid pACYC184 (ref. 24) The difference between these two values is indicated in the second column as a net per cent of the added label which was bound to filters It is taken as a measure of readthrough transcription beyond the attenuator.

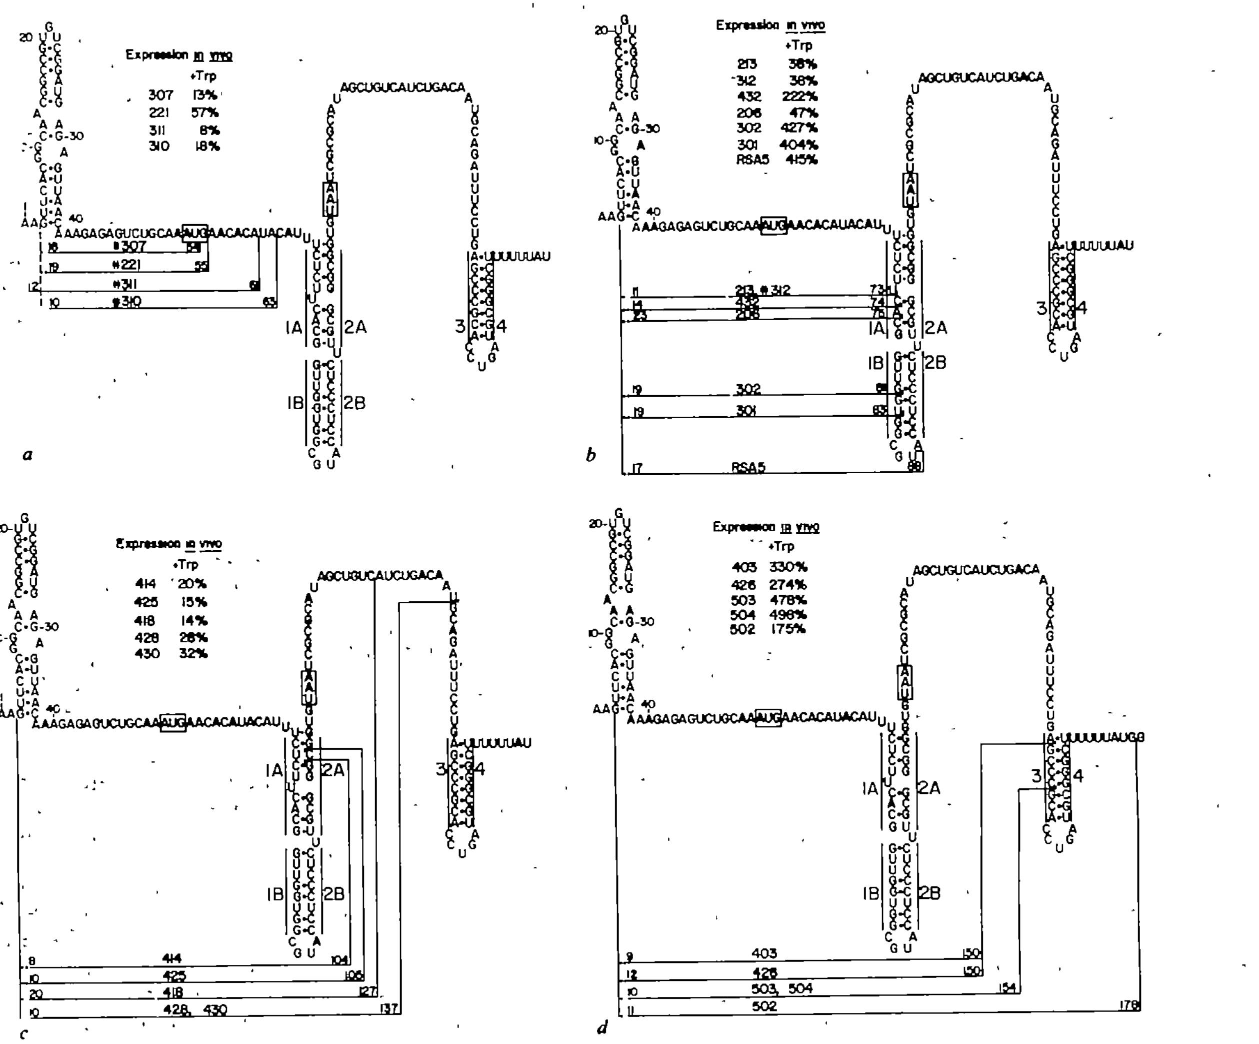

Fig. 2. Deletions in the *S. marcescens trp* leader region that remove the putative translation start codon and regions beyond, increase or decrease transcription termination at the attenuator. Small numbers at the end of the deletion bars indicate the outermost positions of the deleted nucleotides. Deletions are grouped according to the position of the right-hand endpoints. Expression *in vivo* represents the level of *trpE*-encoded anthranilate synthetase produced in *E. coli* strains carrying a single copy of the mutant *S. marcescens trp* leader region followed by an intact *trpE* gene. The numbers correspond to the per cent of the wild-type (*S. marcescens*) *trpE* expression in the same strain (W3110 *trpR* Δ*trpLE1413 tnaA2*/λgtSm4 wild type) grown with an excess of tryptophan. The results are averaged from at least three separate experiments. The experimental error is 20% of the values shown. For the determination of *trpE* enzyme levels the strains were grown at 30 °C in minimal medium[25] supplemented with 0.1% glucose, 0.05% acid-hydrolysed casein and 50 μg ml^{-1} of L-tryptophan. Cells were collected at a density of 6×10^8–7×10^8 per ml, washed with saline, resuspended in 0.1 M Tris-HCl (*p*H 7 8) and disrupted by sonication. Cell debris was removed by centrifugation and the levels of anthranilate synthetase component I were determined in the ammonia assay[26]. DNA sequence analyses were carried out by the method of Maxam and Gilbert[27]. *a*, Deletions which end before segment 1 cause superattenuation (see accompanying paper)[18]. *b*, Deletions which end in or near segment 1B generally cause high readthrough. *c*, Deletions which end between segments 2 and 3 cause increased termination. *d*, Deletions which remove all of segment 2 and part or all of segments 3 and 4 cause high readthrough.

exception to this pattern. Note, however, that the deletion in 206 allows nucleotides 17–20 (CCGU) to pair with segment 2A at positions 104–107 (GCCG), thereby conceivably restoring hydrogen bonding between segments 1 and 2.

The free energy of formation for the wild-type base-paired 1:2 structure, calculated by currently recommended rules[19], is $\Delta G = -4$ kcal mol^{-1}. We believe that this value may be a gross underestimate of the true stability of this structure. We feel that the theoretical bases for stability predictions do not take into account the unusual sequences present in structure 1:2. In particular, the high pyrimidine content of the interior loops and the possible contribution of tertiary interactions may markedly influence stability. From our observations we tentatively conclude that structure 1:2 is moderately stable. An alternative hypothetical structure can be deduced for 1:2, and will be discussed below.

Deletions which remove segments 1 and 2 result in superattenuation—*trpE* expression four- to sevenfold lower than that in wild-type (Fig. 2*c*). The behaviour of this class of deletions establishes that the terminator, 3:4, is the only secondary structure signal necessary to cause transcription termination at the attenuator. Deletion of increasing portions of the loop region separating segments 2 and 3 confirm this conclusion; the extent of termination in mutants of this class is essentially the same as in deletion mutants that simply remove the translation start codon. Thus, superattenuation is observed whether or not 1:2 exists and can form.

The final set of deletions are those having endpoints in region 3 or beyond 4 (Fig. 2*d*). These result in high levels of operon expression, suggesting that there is little or no termination. Surprisingly, deletions 403 and 426 largely eliminate termination yet they disrupt only one base pair of structure 3:4 (A–U, nucleotides 150 and 170). These deletions change the calculated ΔG for 3:4 from −21.6 kcal mol^{-1} to −19.4 kcal mol^{-1}. We do not know why these mutations have such a profound effect. In *E. coli*, the predicted stability of structure 3:4 in termination-deficient mutants that show two- to fourfold increased expression of the operon *in vivo* is reduced by ~50% (refs 5, 20). All these mutations, unlike the *S. marcescens* deletions, affect the central GC pairs of the terminator. Deletion 502 removes the entire terminator but the observed expression in this mutant is not as high as in deletion 503. Studies *in vitro* indicate that there is no transcription termination on templates with this deletion (I.S. and C.Y., unpublished). We hypothesize that as this deletion ends 26 nucleotides upstream from the *trpE* structural gene, it interferes with ribosome binding and initiation of translation of *trpE* mRNA.

A curious effect of tryptophan starvation

All the deletions described here remove the start codon for the leader peptide and consequently eliminate translation of the peptide-coding region. Nevertheless, we have found that every deletion mutant in which there is transcription termination at the attenuator responds to tryptophan starvation by exhibiting a 1.5–2-fold increase in anthranilate synthetase levels (data not shown). In contrast, deletion mutants that do not terminate transcription at the attenuator have identical anthranilate synthetase levels whether starved of tryptophan or not. The explanation for this observation is unknown. Perhaps the small increase is due to some general effect of starvation on transcription termination; this effect is being investigated further.

Alternative RNA secondary structures in the regulation of attenuation

We have examined the effects on gene expression of 21 deletions with endpoints entirely within the leader region of the *trp* operon of *S. marcescens*. Although our functional analyses were carried out in *E. coli*, we have shown that in this heterologous system the wild-type *trp* operon of *S. marcescens* is regulated by attenuation in a qualitatively identical manner to the *trp* operon of *E. coli*. We find that deletions within the *S. marcescens* leader region which remove the leader peptide start codon and different segments of the region beyond may increase, decrease or have no effect on transcription termination at the attenuator. The positions of the deletion endpoints and their effect on gene expression are summarized in Fig. 3. It is apparent that as the right-hand endpoint extends further into the leader region, transcription termination increases, then decreases, then increases again and finally is eliminated entirely compared with the wild-type. These findings are most readily explained in terms of the alternative secondary structure models schematically represented in Fig. 1.

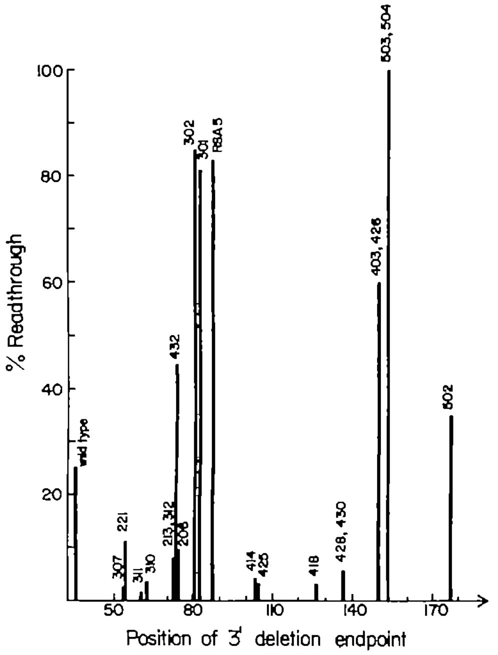

Fig. 3 Positions of right-hand deletion endpoints in *S. marcescens trp* leader mutants and the effect on *trpE* expression. The height of each bar represents the level of anthranilate synthetase produced during growth with tryptophan relative to the level observed in deletion mutants 503 and 504 (set at 100). The range of *S. marcescens trp* operon expression varies 30–60-fold in different deletion mutants. Maximum transcription termination is observed in the translation-defective deletion mutant, 311, in which readthrough occurs at ~10% that in wild type. By comparison, in the *E coli* initiation codon point mutant, *trpL29*, readthrough is ~25% that in wild type[20]

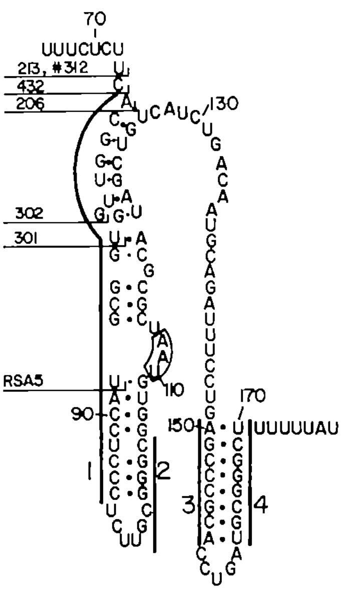

Fig. 4 An alternative potential secondary structure in the *S. marcescens trp* leader transcript The secondary structure labelled 1:2 is formed by the pairing of segments of the transcript other than those paired in the structures depicted in Figs 1 and 2 Note that segment 2 is identical in all the structures and can pair with either segment 1 or segment 3. The endpoints of the deletions described in Fig. 2*b* are indicated. Some of these deletions reduce termination at the attenuator (see text). The calculated ΔG value for the hypothetical structure shown involving nucleotides 75–126 is −23 kcal mol^{-1}, and for the portion of the structure involving nucleotides 88–109, −13 kcal mol^{-1}. In making these estimates it was assumed that a G · U base pair is equivalent to an A · U base pair.

Another potential 1:2 RNA secondary structure exists (Fig. 4); this structure is predicted to be more stable than structure 1:2 as drawn in Figs 1 and 2. However, the effect of deletions 432, 302 and 301 is inconsistent with the structure in Fig. 4, for these deletions should not reduce termination if structure 1:2 in Fig. 4 is correct, but should relieve termination according to structure 1:2 in Figs 1 and 2. In view of our findings, we prefer the secondary structure presented in Figs 1 and 2.

Several studies on attenuation in the *trp*[5–7,20,21] and *his*[22,23] operons support the assumption that changes in the secondary structure of the leader transcript mediate the regulatory response. The experiments described here were designed to test this assumption. The results obtained are in agreement with the secondary structure model and the expected consequences of deleting specific RNA segments that can participate in base pairing. Thus, we believe that the ribosome translating the leader transcript has no role other than sterically to prevent base pairing by the segment of RNA with which it is in contact. This conclusion is supported by the results of *in vitro* transcription studies with restriction fragments bearing the *Serratia* deletions described here (I.S. and C.Y., in preparation). In these studies we have found that in a minimal transcription system consisting of restriction fragments and RNA polymerase, the same pattern of increased termination and termination relief seen *in vivo* with our deletion mutants is reproduced *in vitro*. We conclude, therefore, that when the RNA terminator forms, the transcribing RNA polymerase molecule recognizes that structure and transcription termination occurs. The role of translation, ribosome stalling and alternative RNA secondary structure formation, is simply to regulate formation of the terminator.

These studies were supported by grants from the USPHS, the NSF and the American Heart Association. I.S. was a postdoctoral fellow of the American Cancer Society. C.Y. is a Career Investigator of the American Heart Association. We thank Magda van Cleemput for help with DNA sequence analyses and Roberto Kolter for stimulating discussions and a critical reading of the manuscript.

Superattenuation in the tryptophan operon of *Serratia marcescens*

Iwona Stroynowski*, Magda van Cleemput & Charles Yanofsky

Department of Biological Sciences, Stanford University, Stanford, California 94305, USA

Deletions were generated in vitro *in the leader region of the tryptophan operon of* Serratia marcescens *and subsequently incorporated into the* Escherichia coli *chromosome in single copy form. Deletions which removed the translation start codon for the leader peptide or which ended in the ribosome recognition region preceding the leader peptide coding segment, caused superattenuation, that is, increased transcription termination at the attenuator. Apparently, the capacity to initiate translation of this coding region modulates expression of the operon.*

THE tryptophan (*trp*) operon of each of the six enterobacterial species that have been studied (refs 1–5 and M. Blumenberg and C.Y., in preparation) is controlled at the level of transcription termination by a mechanism called attenuation. In each *trp* operon, translation of a short peptide coding region in the initial, leader segment of the transcript seems to regulate the formation of alternative secondary structures, one of which is recognized by RNA polymerase as a transcription termination signal. It has been proposed that in cells which have an adequate supply of Trp-$\mathrm{tRNA}^{\mathrm{Trp}}$, translation proceeds to the end of the coding region, thereby favouring formation of the RNA secondary structure that serves as the termination signal. However, when most of the cellular $\mathrm{tRNA}^{\mathrm{Trp}}$ is uncharged, the ribosome translating the peptide coding region of the transcript stalls at one of two adjacent Trp codons, generating an alternative RNA secondary structure that excludes formation of the termination structure.

Studies with *Escherichia coli* mutants defective in the regulation of transcription termination at the *trp* operon attenuator[6] suggest that translation of the peptide coding region is utilized for two purposes. First, translation mediates the regulatory response to changes in the level of charged $\mathrm{tRNA}^{\mathrm{Trp}}$. Second, translation establishes the moderate level of transcription read-through that is characteristic of cultures growing with excess tryptophan. Thus, there is fourfold increased transcription termination at the attenuator of a leader mutant in which the start codon for the leader peptide has presumably been inactivated. This observation suggests that attenuation is modulated by the ability to initiate translation as well as by tryptophan availability.

Here we describe the production of deletions within the *trp* leader region of *Serratia marcescens* and analyse the effects of those that alter RNA segments believed to be essential for initiation of synthesis of the leader peptide. Our findings indicate that elimination of translation initiation results in increased transcription termination at the attenuator, or superattenuation.

Directed *in vitro* deletion mutagenesis in the *trp* leader region of *S. marcescens*

Deletions were generated around the *Hpa*I site at position 34/35 of the leader region by limited digestion with *Bal*31 exonuclease[7] (Fig. 1*a*). This exonuclease acts quasi-processively at both 3′ and 5′ termini of double-stranded DNA to release 5′ mononucleotides; digestion predominantly produces blunt ends[7]. There are two *Hpa*I sites in the *trp* regulatory region; *trp* repressor was added to protect the *Hpa*I site in the promoter. However, as *Bal*31 digestion of the promoter would inactivate it, strains with such deletion plasmids would not be detected in the subsequent step requiring *trpE* expression. Following *Bal*31 digestion, ligation and transformation, plasmids were isolated from individual transformants and screened for deletions in the desired region by examining the size of the single *Eco*RI fragment that contains the *trp* regulatory region, and by mapping restriction sites within the fragment. The distribution of deletion endpoints in the mutants was further characterized by DNA sequence analysis[8] and is shown in Fig. 2. There is asymmetry in the length of the segment deleted on either side of the *Hpa*I site, presumably because deletions extending into the *trp* promoter are not recovered.

Expression of deletion mutants

The effect of the deletions on attenuation was determined after introducing each deletion into the chromosome, in single copy form, as outlined in Fig. 1*b*. Briefly, phage $\lambda gtSm4Cm^r$ was grown in a bacterium with each deletion plasmid and the lysate obtained was used to transduce a *trpR trpE* deletion strain to Trp$^+$. Control experiments showed that lysogens prepared with a homologous phage that has *trpE*$^+$ and the 22 base pairs

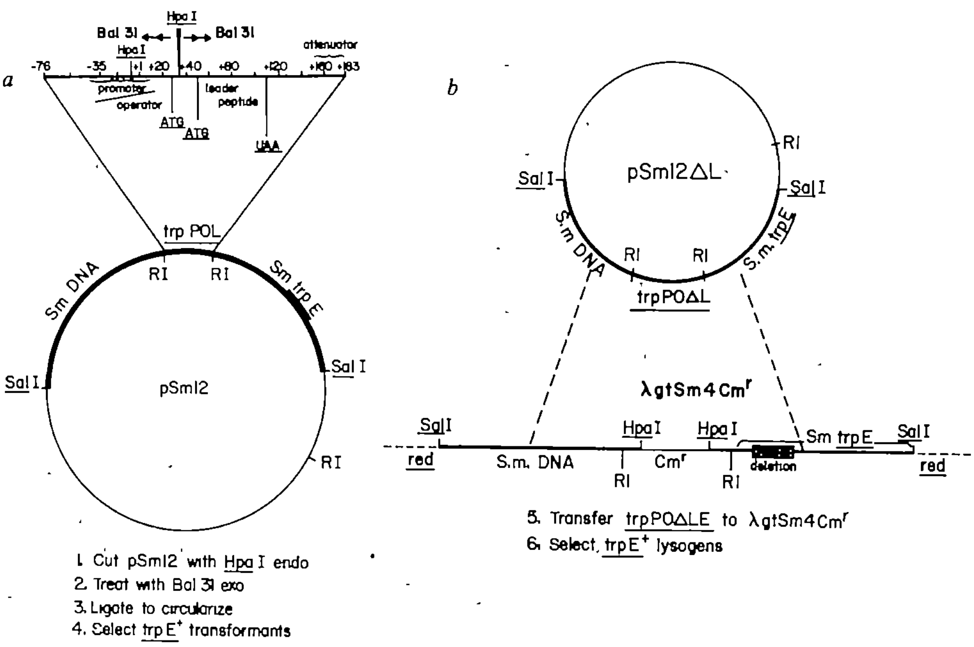

Fig. 1 Deletion mutagenesis of the *trp* leader region of *S. marcescens* (*a*) and introduction of deletions into the *E. coli* chromosome (*b*). Deletions were generated in plasmid pSM12[4]. The *EcoRI* fragment containing the regulatory region of the *S marcescens trp* operon is shown enlarged at the top of the figure (*a*). Number +1 corresponds to the presumed site of transcription initiation The 'in-phase' AUG and UAA codons indicate the potential coding region for the leader peptide. Deletions were generated around the *Hpa*I site at position 34/35. To ensure preferential cutting at this site, partial digestion with *Hpa*I was done in the presence of *E. coli trp* repressor, which is known to protect the *Hpa*I site at postion −11/−12 from cleavage[4]. 20 μg of partially digested DNA was treated with *Bal*31 exonuclease in a reaction mixture containing 20 mM Tris-HCl *p*H 8.1, 200 mM NaCl, 12 mM $CaCl_2$, 12 mM $MgSO_4$ and 1 mM Na_2EDTA in a 300 μl total volume. The reaction mixture was incubated on ice and samples were taken after 1 and 15 min, the mixture was transferred to room temperature, and samples were taken after an additional 1, 4 and 6 min The reactions were stopped by adding 10 mM EDTA *p*H 8 and the DNA precipitated with ethanol. 1 μg of DNA from each sample was resuspended in 200 μl of ligation buffer (60 mM Tris-HCl *p*H 7.6, 10 mM $MgCl_2$, 1 mM ATP). The mixtures were incubated in the presence of T4 DNA ligase for 2–4 h at room temperature and used directly to transform *E. coli* strain JA221 (C600 r^-m^+ Δ *trpE5 thr leu recA*) to Trp^+. The plasmid DNA from the transformants was analysed by digestion with *Eco*RI and *Hin*fI restriction enzymes. Approximately 25% of the plasmids carried a deletion of the *Hin*fI site at postion 43/47 and preserved the integrity of the *Eco*RI sites bordering the *trppoL* region These plasmids were used to transform W3110 *trpR* Δ *trpE5 tnaA2* to Trp^+ and were analysed further by sequencing[8]. The regulatory region containing each deletion was transferred to phage λ and then into the *E coli* chromosome by general recombination and lysogenization as shown schematically in *b*. To promote recombination, *E. coli recA*⁺ strains containing the mutant plasmids were infected lytically with bacteriophage λgtSm4Cmʳ. The lysates were used to lysogenize strain W3110 *trpR* Δ *trpE5 tnaA2* at a permissive temperature (30 °C). The recombinants were identified as Trp^+ prototrophs, temperature sensitive and unable to grow in the presence of 25 μg ml^{-1} of chloramphenicol To ensure single copy lysogeny the infections were performed at low multiplicity (<0.001). Bacteriophage λgtSm4Cmʳ was constructed by recombinant DNA techniques using DNA from λgt4 (Ron Davis, personal communication), pSM12[4] and pACYC184[17].

preceding it intact, but lacks the *S. marcescens trpPOL Eco*RI fragment, have less than 0.1% of the wild-type level of anthranilate synthetase (*trpE*⁺) activity and are phenotypically Trp^-. Thus, *trpE*⁺ expression from our leader deletion lysogens must originate at the *trp* promoter in the *Eco*RI segment. This conclusion was substantiated by introducing *trpR*⁺ into some of these strains and showing that *trpE* expression was under *trp* repressor control.

In Fig. 3 we indicate the sequence of the leader transcript segment containing each deletion junction. Also shown is *trpE* expression relative to that of a control culture containing the unaltered wild-type leader region. The first four deletion mutants, 204–208, have the wild-type sequence in the ribosome binding region for leader peptide synthesis[9]. These strains exhibit wild-type levels of anthranilate synthetase and respond to tryptophan starvation by a four- to five-fold increase in synthetase levels. The fifth deletion mutant, 102, has half the wild-type levels both in the presence of and following starvation for, tryptophan. Note that the sequence in the ribosome binding region is altered although homologous GAG sequences are located slightly earlier than in wild type. We interpret the findings with this mutant as indicating that translation initiation does occur at the 102 AUG start codon but is somewhat reduced in frequency relative to that of the wild type.

The second group of deletions, represented by seven independently isolated deletion plasmids, have a considerably different effect. Strains with these deletions have 8–10-fold reduced anthranilate synthetase levels compared with the wild type;

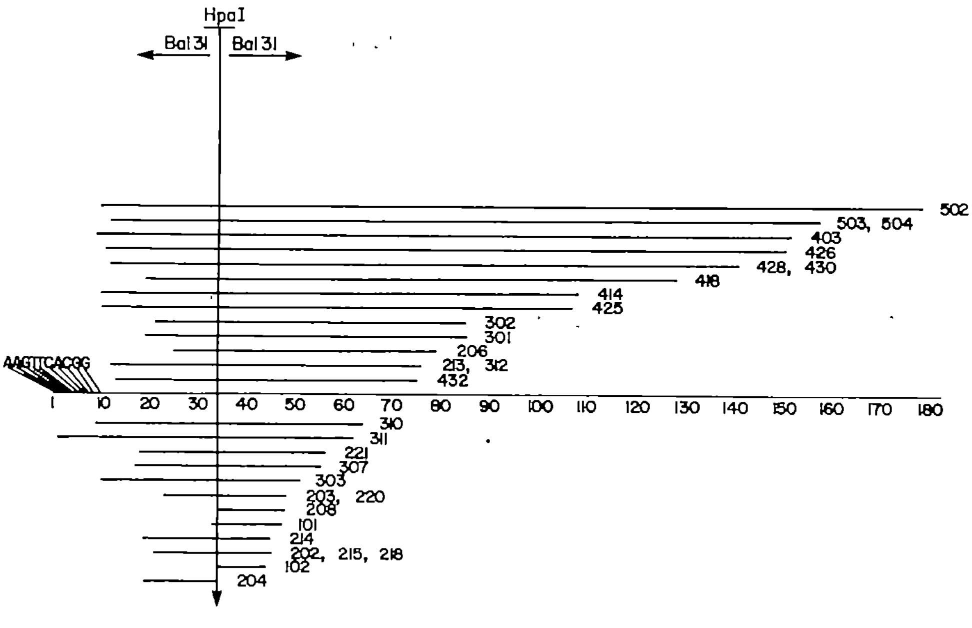

Fig. 2 Distribution of deletion endpoints in the *S. marcescens trp* operon leader region Numbering is from the presumed site of transcription initiation. The site of *Hpa*I cleavage and direction of *Bal*31 digestion are indicated by arrows The nucleotide sequence of the first 10 residues is shown on the left.

Fig. 3 The nucleotide sequence of the segments of the leader transcript containing deletion junctions. The former positions of the fused nucleotides are indicated by small numbers. The mutant sequences are aligned at wild-type position 55 and compared with the wild-type sequence at the top and bottom of the figure. The presumed initiation codon is boxed by a heavy line, while the AUG which is thought not to function as a translation initiation codon is boxed by a thin line. Nonsense UGA codons which are in phase with AUG codons are bracketed. Complementarity to 16S rRNA is underlined by wavy lines. Vertical broken lines show the region thought to be important in ribosome binding and initiation of leader peptide synthesis. Numbers referring to expression *in vivo* refer to per cent of wild-type *trpE* expression measured in the same strain containing the wild-type region. Growth conditions and assays of *trpE* enzyme activity are described in Fig. 2 legend of the accompanying paper.

these levels are increased only slightly when the strains are starved of tryptophan (see accompanying paper[10]). These deletions have in common changes in the nucleotide sequence of the ribosome binding region. However, in each case we can indicate some new sequence that is complementary to the 3′ end of 16S rRNA. We interpret these findings as indicating that in these deletions there is little or no translation initiation at the normal AUG start codon, and that the absence of translation is responsible for reduced *trpE* expression. The final mutant, 307, deletes through the start codon; it behaves indistinguishably from the preceding group of seven.

At the bottom of the Fig. 3 we present the sequence of the first 28 nucleotides of the transcript. There is a potential AUG start codon at positions 26–28 that is in-phase with the AUG at 53–55. We believe that this AUG codon is not used as a site of translation initiation, for the following reasons. First, deletions which remove this region are phenotypically indistinguishable from wild type. Second, fusion of this region in deletions 101 and 208 places the first AUG out of phase with the second AUG, but in-phase with a UGA stop codon that overlaps that second AUG. If the first AUG were used as a site of translation initiation we would expect that translation from this site would interfere with in-phase translation of the tryptophan codons, which must occur in view of the tryptophan starvation response. Thirdly, if translation were initiated in wild type at the first AUG, several amino acid residues including Arg would be added at the amino-terminal end of the leader peptide. Yet arginine starvation relieves transcription termination at the attenuator[10], implying that in the absence of this amino acid a ribosome can reach—and stall at—the Arg codon located immediately following the tandem Trp codons. Finally, there are no sequences resembling a Shine–Dalgarno sequence in the appropriate segment of the transcript (Fig. 3).

Significance of reduced operon expression in mutants with altered leader peptide translation initiation regions

The increase in transcription termination at the attenuator in deletion mutants implies that in wild type there is some mechanism responsible for establishing a moderate level of transcription readthrough and hence operon expression in cultures growing with excess tryptophan. The superattenuating deletions have in common changes in the sequence of nucleotides believed to be required for efficient ribosome binding; these changes presumably result in reduced initiation of synthesis of the leader peptide.

Alternatively, the leader segments could contribute to an RNA secondary structure involved in regulation. However, as deletions 204, HPA2, 101 and 208 lack segments of the same region yet exhibit wild-type expression and response, it seems likely that a defect in translation initiation is responsible for the observed reduction of expression. This interpretation leads to the conclusion that normal translation of the leader peptide coding region proceeds concomitantly with transcription and that ribosome movement or position is responsible for the moderate level of expression seen in wild type. In accordance with the model proposed previously[2] and supported by the findings in the accompanying paper[10], we conjecture that the anti-termination secondary structure, 2:3 forms occasionally when a ribosome translates the peptide coding region. This could occur by transitory masking of segment 1 by a sluggish ribosome, occasional pairing of segments 2 and 3 as the ribosome dissociates from the stop codon, or masking of segment 1 by a second ribosome on the transcript. The role of transcriptional pausing[11] in the synchronization of transcription with translation must be investigated before these or other explanations can be realistically distiguished.

Regardless of the basis for the moderate expression in wild type, our findings indicate that superattenuation could be used by the bacterium to achieve a level of *trp* operon expression well below that characteristic of cultures growing in the presence of excess tryptophan. Thus, if a cell were incapable of initiating

Fig. 4 A sequence of possible evolutionary events leading to the present-day nucleotide sequences of the *trp* leader regions of various enterics. In reality the postulated deletion event would have taken place in a common ancestor of the Enterobacteria, which could have had a nucleotide sequence somewhat similar to that of *S. marcescens.*

translation of the leader coding region, for whatever reason—a deficiency of formylating activity, lack of an initiation factor or a drastic decrease in the number of available ribosomes—this would be recognized as a signal to superattenuate. If this feature is common to all instances of attenuation control of amino acid biosynthetic operons, it is apparent that attenuation may be used generally to attain a greater range of operon expression than had previously been thought possible. Two mutations of the *his* operon leader region support this hypothesis[12,13]. They are phenotypically similar to our superattenuating deletions and are altered in the region potentially involved in translation initiation in *his* leader peptide synthesis. Studies on *trp* mRNA synthesis in *trpR* strains of *E. coli* following a nutritional or carbon source shift-up suggest that superattenuation may occur naturally in the wild-type operon[14].

Tryptophan starvation in strains with either the *E. coli* or *S. marcescens* wild-type *trp* operon results in operon expression approaching the level seen in leader deletion mutants that lack the attenuator. This finding suggests that in tryptophan starvation conditions translation initiation must be so efficient that virtually every *trp* mRNA molecule has a ribosome stalled over the Trp codons of the leader transcript. The view that the leader ribosome binding site is efficient is supported by *in vivo* and *in vitro* studies[15,16].

Possible duplication in the *S. marcescens* leader region

Comparison of the initial segment of the *trp* leader regions of several enterobacteria (Fig. 4) reveals that *S. marcescens* seems to have a 25-base pair insert. This region in *S. marcescens* contains a putative start codon that is in phase with the functional start codon at 53–55 (Fig. 2). The role, if any, of this extra segment is brought into question by the findings discussed earlier that deletions that remove this segment have no detectable effect *in vivo* on attenuation and its regulation. The RNA segment bases 3–19 can form a weak secondary structure with segment base 23–37 (see accompanying paper[10]); however, we know of no functional role for this pairing. We must consider the possibility, therefore, that the insert is a remnant of an ancestral sequence that once had a function. The sequence of a segment of the insert is strikingly similar to a proximal sequence, suggesting that the insert arose as a consequence of duplication. Presumably, a portion of one of the duplicated segments was deleted in the evolution of leader regions of the *E. coli* type. A sequence of possible evolutionary events is depicted in Fig. 4. One might imagine that the duplication arose initially in response to selection for a more efficient ribosome binding site or a requirement for simultaneous translation by two ribosomes. Some time thereafter the weaker of the two ribosome binding sites was inactivated to give the present-day sequence of *S. marcescens*, or deleted to produce the *E. coli* arrangement. In this regard it is of interest that *trpG* and *trpD* are separate, adjacent genes in *S. marcescens*[4] whereas in *E. coli* and other enterobacteria these genes are fused in what seems to be a more advantageous arrangement. Both this instance and the existence of the apparent non-functional insert in the *S. marcescens trp* leader region suggest that the *trp* operon of *S. marcescens* may be more primitive than its counterpart in *E. coli*. Support for this view awaits specific tests of the functional significance of the different genetic arrangements.

These studies were supported by grants from the USPHS, the NSF and the American Heart Association. I.S. was a Postdoctoral fellow of the American Cancer Society. C.Y. is a Career Investigator of the American Heart Association. We thank our colleagues for critical reading of this manuscript.

Optical identification of X-ray source H0139−68 with an AM Herculis-type system

N. Visvanathan & A. Pickles

Mount Stromlo and Siding Spring Observatories,
Research School of Physical Sciences, Australian National University,
Private Bag, Woden Post Office, ACT 2606, Australia

We report here the identification of the soft X-ray source H0139−68 with a star at RA = 01 h 39 min 37.5 s, dec = −68° 08′ 32″ (1950). Time-resolved spectrophotometry of the star over 3 h shows a V magnitude variation between 14.9 and 16.4 with a period of ~110 min. The spectra are dominated by emission lines of neutral hydrogen, neutral helium and singly ionized helium throughout the period. The line ratios of the Balmer lines H_γ/H_β and the He I lines are flatter relative to case B recombination values, while the He II ratios are consistent with optically thin recombination. The mean radial velocity of the emission lines varies with the photometric period roughly sinusoidally from 340 to −150 km s^{-1}. The continuum is very red at maximum light, flat at minimum and shows strong polarization. These optical characteristics of the candidate star are similar to those of the magnetic cataclysmic variable AM Herculis.

The candidate star is marked X in Fig. 1, along with the X-ray source error circle of radius 36 arc s (ref. 1). Spectrophotometric observations of the candidate star were obtained on the night of 6 October 1981, with the 1DPCA[2] at the $f/8$ cassegrain focus of the Mount Stromlo Observatory 1.9-m telescope. We obtained 17 spectra of the candidate star in the time interval 15 h 20 min UT to 18 h 20 min UT, with a

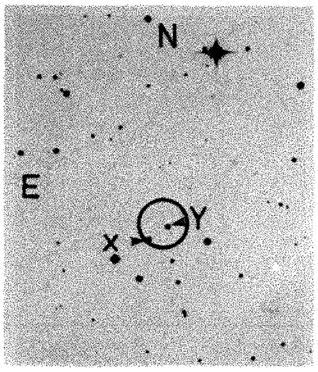

Fig. 1 The circle of diameter 72 arc s defines the X-ray source location, and X marks the optical identification with H0139−68. The coordinates of X are RA = 01 h 39 min 37.5 s, dec = −68° 08′ 32″ (1950). The star marked Y shows a late-type spectrum with no variability.

Table 1 *Line ratios in H0139 − 68*

Brightness phase	H_γ/H_β	He I $\lambda 5,016/\lambda 4,471$	He I $\lambda 5,876/\lambda 4,471$	He II $\lambda 5,411/\lambda 4,686$
Minimum	0.81	0.70	1.16	0.08
Rising	0.87	0.76	1.12	0.05
Maximum	0.83	0.64	1.24	0.05
Falling	0.78	0.67	1.21	0.04

time resolution of 10 min. The spectra cover the wavelength region 4,000–6,100 Å with a resolution of 3.2 Å. The star and sky apertures used had dimensions 3 × 7 arc s with a separation of 160 arc s. The absolute energy distribution of each sky-subtracted, wavelength-calibrated scan was computed by calibration of standard stars[3] observed in the same way as the candidate star. The sky transparency and seeing were good during the night, and the mean relative error in absolute flux is estimated to be 5%. Star Y in Fig. 1 was also observed, and found to have a late-type stellar spectrum, with no evidence for variability.

The apparent magnitude in the conventional *V* band has been computed for each scan, and is plotted as a function of time in Fig. 2*a*, where both universal time (UT) and Julian day (JD) of observation are given; 2σ error bars and the observational dwell time are also indicated. Figure 2*b* shows the corresponding variation with time of the fluxes computed in the lines of H I, He I and He II.

The significant feature in the visual light curve (Fig. 2*a*) is the deep minimum observed which is as much as 1.5 mag in amplitude and appears to repeat after ~110 min. Recent observations of the star[4] support the reality of this period. The emission line fluxes (Fig. 2*b*) also show variation with time, though with smaller amplitudes. Furthermore, the radial velocity of the emission lines (Fig. 4) shows a sinusoidal variation with a period about 110 min.

The above behaviour reveals that Star X is an eclipsing system where the deep minimum in the light curve corresponds to the mid-point of the primary eclipse. The unusual length of the primary eclipse (about 0.5 period) as well as the domination of the spectra during this period by emission lines indicate that the change of light that we see during the eclipse is not due to the primary star but mostly from a heated region a few radii from the primary. AM Herculis exhibits a similar light curve with a period of 186 min (ref. 5).

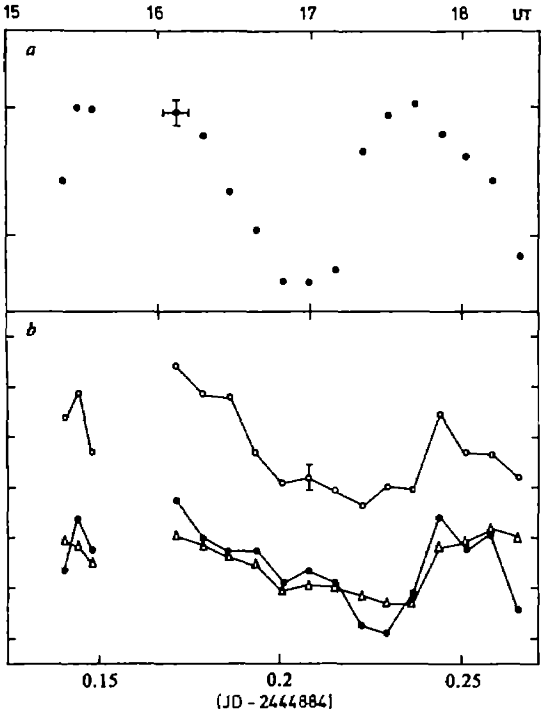

Fig. 2 *a*, The spectrophotometrically derived apparent *V* magnitude light curve for the star X: 2σ error bars, and observation dwell times are shown. A period of ~110 min is apparent. *b*, The emission line fluxes as a function of time of observation: 2σ error bars are shown. ○, H I; ●, He I; △, He II.

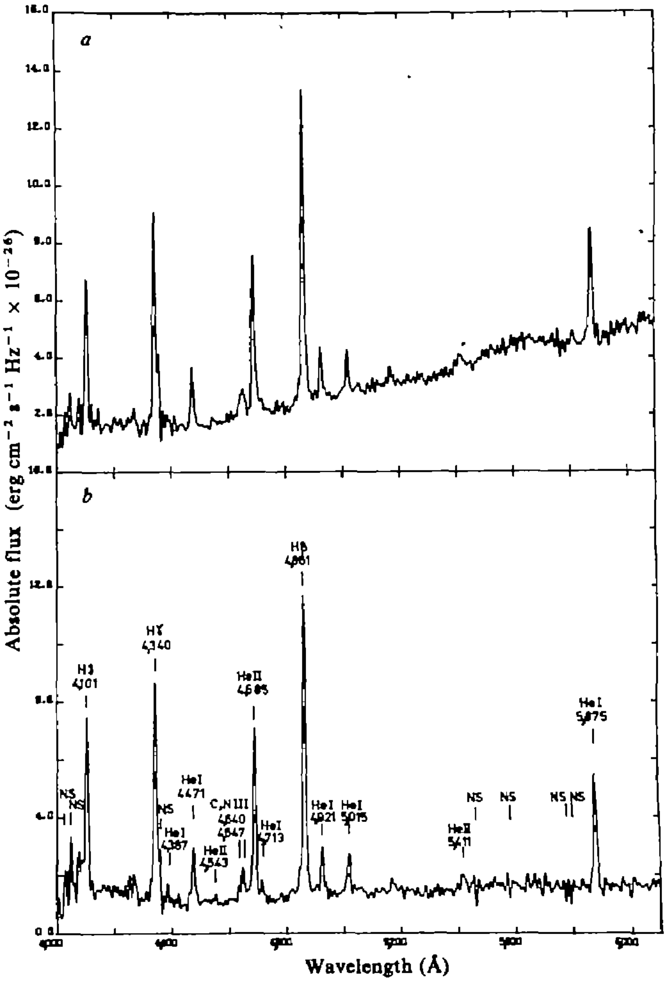

Fig. 3 The spectrum of star X at maximum (*a*) and minimum (*b*). Each spectrum is the average of four 10-min observations, and the spectra have been Fourier filtered to remove high-frequency noise. Emission lines due to H I, He I, He II, C III and N III are marked, residual night-sky features are labelled NS. The continuum is very red at maximum, and flat at minimum. The line-widths are smaller at minimum, as indicated by the resolved N III (λ4,640), C III (λ4,647) feature.

Figure 3 shows the absolute energy distribution of star X during its maximum and minimum brightness phases. Each spectrum shown is the average of four 10-min scans selected from the light curve at appropriate phases. It can be seen that the spectra are dominated by emission lines of H I, He I and He II: a feature due to N III (λ4,640) and C III (λ4,647) which is commonly seen in X-ray counterparts, is also apparent and is resolved at minimum. A detailed look at all the spectra indicates the presence of emission lines throughout the binary period (Fig. 2*b*).

The line ratio of the Balmer lines H_γ/H_β, given in Table 1, is found to vary little with phase. It is flatter relative to the case B recombination value for an optically thin gas[6]. This is true also for the He I lines and indicates that the emission regions observed are optically thick in these lines. Also the high value of 0.8 for the ratio of H_γ/H_β is suggestive of collisional excitation as well and implies an electron density as high as 10^{13} cm^{-3} in the line emitting regions[7].

Thus the emission spectrum of H I and He I reveal the presence of regions in the system which are optically thick and collisionally dominated. On the other hand, He II line ratios (Table 1) are consistent with optically thin recombination radiation indicating stratification of the line emitting regions.

Note that we do not see any stellar absorption features in the spectra at any phase. We deduce that any underlying stellar continuum contribution is <10% of the measured flux implying an apparent V_{mag} of 19 or fainter for any unseen stellar system.

More information on the line-emitting region can be obtained from the radial velocity data. The stronger H I, He I and He II lines have been fitted with gaussians to determine the line centres and line widths for each line of each scan separately. The measured line widths (σ of the fitted gaussian, expressed as velocity dispersion) have been corrected for instrumental broadening by quadratically subtracting the measured arc line width of 130 km s^{-1}. We are unable to detect any multiple components in the lines at any phase, but the instrumental resolution is insufficient to detect the presence of sharp components as seen in AM Herculis[8]. The radial velocity curve given in Fig. 4*a* shows a roughly sinusoidal variation with mean amplitude of $2K = 490$ km s^{-1}, asymmetrically distributed about velocity zero (with respect to the Sun). The line widths of the emission lines (Fig. 4*b*) also change with phase, with both maximum recessional velocity and maximum line width occurring near maximum light. The higher ionization species He I, He II display higher maximum recessional velocity and higher broadening at maximum than do the H I lines. These differences are significantly greater than the mean errors for single velocity or width determinations, which are indicated in Fig. 4*b*.

Part of the asymmetry in the radial velocity curve may be due to the unknown systemic velocity, but the large amplitude and variation in the line width with phase imply the presence of a gas stream. The radial velocity of the system is then dominated by streaming motions of a single mass transfer stream directed towards the primary. The orbital notion component for a typical system (with a red dwarf of mass ~0.2 $M_\odot$ and a white dwarf of mass 0.3 $M_\odot$) is derived as 80 km s^{-1}, with a maximum of 170 km s^{-1} for a white dwarf mass of ~1.4 $M_\odot$. Higher orbital velocities imply the presence of a large mass secondary which would be too luminous not to be seen. This mass transfer stream is consistent with models of AM Herculis[9,10] and VV Puppis[11] in which a single mass transfer stream from a late-type star overflowing its Roche Lobe, is funnelled down onto a magnetic white dwarf primary, with the magnetic field lines constraining the mass flow. In this model the velocity width would be due to the line-of-sight sampling of a range of velocities along the falling gas stream. The varying angle between the line-of-sight and the gas stream would account for the variation in line width with phase. The higher maximum recessional velocity and larger width of the higher ionization species, indicates that they originate closer to the primary, where the velocities are higher.

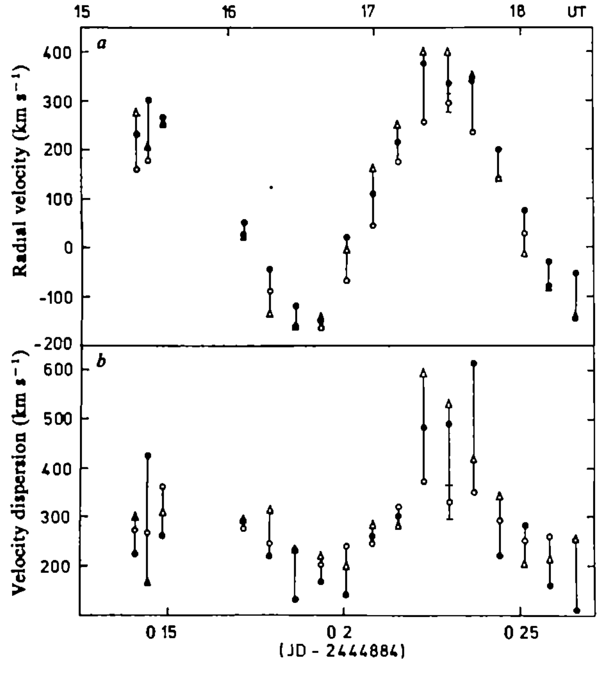

Fig. 4 *a*, The emission line radial velocities (w.r.t. Sun) of H I (○), He I (●) and He II (△) as a function of time of observation: 2σ error bars for a single observation are shown. *b*, The velocity dispersion (σ of fitted gaussian) of the emission lines as a function of time of observation. The instrumental broadening measured on arc lines has been quadratically subtracted. This figure shows that both maximum radial velocity and maximum velocity dispersion are higher for higher ionization species. There is some indication of phase shift between the different species.

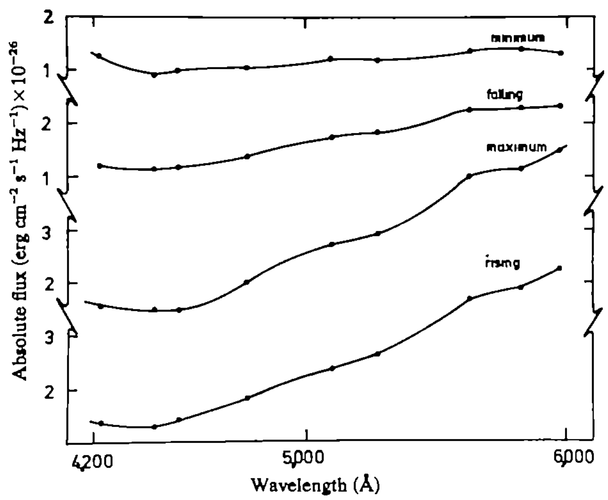

Fig. 5 The continuum flux as a function of phase. The marked points are the mean fluxes in regions away from emission lines, with freehand fits to the points shown. There is indication of cyclotron absorption troughs at maximum, at λ4,500 and λ5,400.

The absolute energy distribution in the continuum between 4,200 and 6,000 Å has been computed by averaging the line-free regions of each spectral scan, and plotting these points against wavelength for four different parts of the light curve (Fig. 5). It can be seen that the continuum is reddest during the rising and bright phases of the system, while it is flat during the faint and falling phases. This variation of the continuum is also seen in AM Herculis[10] and VV Puppis[11].

If we accept the model of matter transfer onto a magnetic white dwarf primary, then we might expect to see both linear and circular polarization in the optical continuum, due to the presence of cyclotron radiation at optical frequencies. Note that there is a suggestion of cyclotron absorption harmonics at 4,500 and 5,400 Å in the continuum at maximum (Fig. 5) and preliminary linear polarization observations indicate that the continuum is polarized as high as 7% close to maximum[12].

In summing up the evidence for this optical identification, we note that periodic variation of the continuum, line emission, and radial velocity of the candidate star reveals that the star is an eclipsing system. The spectra have bright emission lines of H I and He I originating in optically thick and high density regions in the system. The nearly sinusoidal radial velocity and velocity width variations with phase indicate the presence of a gas stream falling into the primary. The continuum colour varies with phase. Linear polarization of the continuum supports the cyclotron origin for the continuum observed, implying the presence of a magnetic white dwarf in the system[12]. Fast photoelectric photometry of the Star X indicates flickerings on a time scale of 100 s or less[4]. All these observed characteristics of the candidate star are seen in the binary system AM Herculis[10] which has been identified with a soft X-ray source[13]. Within 36 arc s of the Star X there is the X-ray source H0139−68 (ref. 1), a source originally detected with the low energy detectors of HEAO A-2 experiment and found to be highly variable over periods as short as 3 h. No flux was detected above 0.4 keV indicating a soft spectrum. Observations with the image proportional counter of the Einstein observatory confirmed the variability of the source and the presence of flickering on a time scale of 20 s or less.

Thus, the remarkable similarity between Star X and AM Herculis and the presence of the variable X-ray source H0139−68 very near to Star X, establish the Star X, a new AM Herculis type system, as the optical counterpart of H0139−68.

We thank P. C. Agarwal and G. R. Riegler for intimating the position of the variable X-ray source in advance of its publication. A. J. P. acknowledges the support of an Australian National University postgraduate scholarship.

Zonal harmonic model of Saturn's magnetic field from Voyager 1 and 2 observations

J. E. P. Connerney, N. F. Ness & M. H. Acuña

Laboratory for Extraterrestrial Physics, NASA/Goddard Spaceflight Center, Greenbelt, Maryland 20771, USA

An axisymmetric octupole model of Saturn's planetary magnetic field is proposed here. This three parameter model, characterized by the Schmidt-normalized spherical harmonic coefficients $g_1^0 = 21{,}535$ nT, $g_2^0 = 1{,}642$ nT and $g_3^0 = 2{,}743$ nT, is extremely efficient in representing the main magnetic field of Saturn and reconciling the *in situ* magnetic field observations obtained by Pioneer 11 with those obtained by the Voyager 1 and 2 spacecraft. Saturn's unique magnetic field configuration is thus not that of a simple displaced dipole but rather appears to be the axisymmetric part of a complex dynamo field. This result is consistent with Stevenson's model of the interior of Saturn[1], in which the differential rotation of a metallic fluid shell above the active dynamo region attenuates all non-axisymmetric components of the dynamo field.

The first *in situ* observations of the magnetic field of Saturn were obtained by the Pioneer 11 spacecraft in September 1979[2,3]. Charged particle and magnetic field data both revealed a near perfect alignment of Saturn's magnetic dipole and rotational axes. Subsequent spherical harmonic analyses of the Pioneer 11 vector helium magnetometer observations[4] led to a model of Saturn's magnetic field ('Nominal 79 dipole') characterized by a dipole of 0.2 $G-R_S^3$ (where 1 Saturn radius R_S is 60,000 km) aligned with Saturn's rotation axis and offset to the north along the rotation axis by 0.05 R_S. [The units $G-R_S^3$ are dimensionally equivalent to standard units of magnetic dipole moment, the numerical value having been divided by the cube of the planetary radius.] Acuña *et al.*[5] considered an axisymmetric potential expansion of Saturn's magnetic field to order $n=2$ (quadrupole) and obtained from the Pioneer 11 fluxgate observations a g_2^0 coefficient of 1,500 nT, equivalent to a northward displacement of the dipole by ~0.04 R_S.

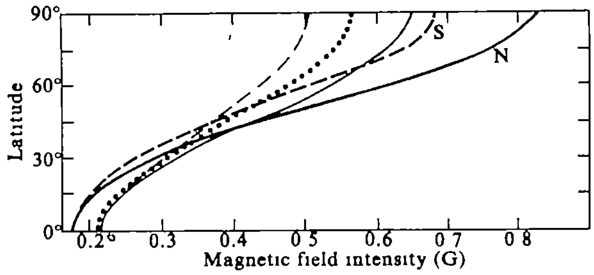

Fig. 1 Magnetic field intensity as a function of latitude on Saturn's oblate (flattening = 10.6) surface. Bold solid (dashed) line is the field intensity at north (south) latitudes corresponding to the Z_3 model (see text). Light lines indicate the field intensity of the offset (~0.04 R_S) dipole model and the dotted line corresponds to a simple centred dipole with 0.21 $G-R_S^3$ moment.

The Voyager 1 encounter with Saturn in November 1980[6] presented a second opportunity to study Saturn's planetary magnetic field. Voyager 1 approached to within 3.07 R_S of Saturn and obtained the first observations of Saturn's magnetic field at high latitudes (to 41°S). Analyses of the Voyager 1 observations confirmed many aspects of Saturn's main field deduced from the Pioneer 11 observations but did not confirm the inferred northward displacement of the dipole[6,7]. The near-equatorial Pioneer 11 approach to within 1.35 R_S yielded observations confined to a more limited range of latitude (±6°). The recent Voyager 2 encounter with Saturn (periapsis: 2.69 R_S) in August 1981[8] provided additional observations of Saturn's field at both high northern and southern latitudes (±30°). We now report the first internal field analyses to include the Voyager 2 vector magnetic field observations.

Our analysis of the magnetic field observations at Saturn uses the traditional spherical harmonic expansion of a scalar potential V from which the magnetic field is obtained through $B = -\nabla V$ (ref. 9). This representation requires that no sources be present within the minimum spherical shell enclosing the observations, and/or the region of representation, that is, that the volume of space $r_{\min} < r < r_{\max}$ contains no electrical currents ($\nabla \times B = 0$). The planetary field is characterized by the Schmidt-normalized coefficients g_n^m, h_n^m associated with the terms in V which decrease with increasing r. The external field is approximated by the first-order expansion corresponding to a uniform external field (G_1^0, G_1^1 and H_1^1). The external field is due primarily to an equatorial azimuthal ring current of ~7×10^6 A flowing between ~8 and 16 R_S (ref. 10). We therefore confine our analysis and modelling to observations obtained inside of 8 R_S. We use 48-s averages of the vector magnetic field data

Table 1 Model fits of Saturn's magnetic field from Voyager 1 and 2 observations

	Unconstrained ($n_{\max}=2$)			Axisymmetric ($n_{\max}=3$)

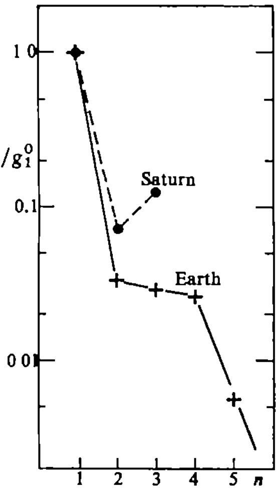

Fig. 2 Relative magnitude of the zonal harmonic (g_n^0) terms of the Earth's magnetic field and the Z_3 zonal harmonic model of Saturn's magnetic field.

obtained at 60-ms intervals to obtain least-squares model fits to the observations, with one exception. Data obtained by Voyager 2 during two brief roll manoeuvres performed near closest approach are included as field magnitude observations only, as the orientation of the spacecraft during these manoeuvres is uncertain (~2°). All of the models were obtained assuming equal weights for the individual observations and using the nonlinear inversion techniques described previously[11].

Our search for an appropriate physical model for Saturn's internal magnetic field can be traced through the model fits tabulated in Table 1. The notation *IjEk* denotes a spherical harmonic expansion with internal (*I*) coefficients to degree and order *j* and external (*E*) coefficients to degree and order *k*. Analyses of the Voyager 1 and 2 observations individually in terms of a physical model including dipole ($n = 1$) and quadrupole ($n = 2$) terms only leads to best fit parameters which, with the exception of the main dipole g_1^0 term, show little reproducibility from one spacecraft encounter to another. In particular, the expected north polar offset (g_2^0) obtained from the Pioneer 11 observations[3,4] is not to be found in the Voyager 1 (V1) *I2E1* model fit, but it does appear in the Voyager 2 (V2) *I2E1* fit (the spatial offsets of an equivalent tilted dipole derived from the *I2* coefficients are listed at the bottom of Table 1). An *I2E1* model fit to all of the Voyager observations results in reduced non-axisymmetric terms ($m \neq 0$) and a g_2^0 appropriate to a northward offset.

These results, and inferences on the axisymmetry of Saturn's magnetic field drawn from the charged particle observations at Saturn[12,13], and current models of Saturn's interior[1], motivated a conceptual model and inversion technique which favours zonal ($m = 0$) harmonics over tesseral ($n > m > 0$) and sectorial ($n = m$) harmonics. We accomplish this by introducing a renormalization of the model parameters $\bar{g}_n^m = g_n^m/100$ ($m \neq 0$). This is equivalent, in our search for a minimum length solution to the least-squares minimization, to *a priori* knowledge of the uncertainties of the parameter estimates[14]. This technique has the advantage that it allows non-axisymmetric components ($m \neq 0$) of the model to be introduced after the zonal harmonics to assess their importance. Details regarding the method of constructing solutions by sequential introduction of (independent) parameters can be found in refs 11, 15.

The results of these 'constrained' model fits are summarized in Table 1. Each solution uses only 3 of the 15 internal field parameters of an *I3E1* spherical harmonic expansion since we found that inclusion of non-axisymmetric internal field terms offered minimal improvement in the model fits. Analysis of the V1 and V2 observations individually in terms of a physical model consisting of zonal harmonics to the order of $n = 3$ leads to very consistent results. That is, the V1 model does an excellent job of predicting the magnetic field observed by V2 in a very different region of space, and vice versa. Thus, this third-order zonal harmonic model behaves as a proper model whereas models including dipole and quadrupole terms only do not.

We therefore propose as a model of Saturn's planetary magnetic field the third-order zonal harmonic model fitted to both V1 and V2 observations, listed in Table 1 and hereafter designated as the 'Z_3' model (zonal of order 3). No equivalent offsets are listed for the axisymmetric models because the relative magnitudes of the derived g_n^0 terms are inconsistent with a simple axially offset of the dipole. The ratio g_3^0/g_2^0 is too large by a factor of ~30 to be attributed to a dipole offset.

The Z_3 model is an extremely efficient representation of Saturn's planetary field, requiring only three parameters. It fits the combined V1 and V2 observations with little more than half the r.m.s. residual of a best-fitting axially offset dipole. Inclusion of a (small) fourth-order zonal harmonic (g_4^0) does not significantly improve the fit to the observations nor does it alter appreciably the values of the Z_3 model parameters. Much of the remaining difference (~3 nT r.m.s.) between the Z_3 model magnetic field and the V1 and V2 observed field is due to external sources (in addition to and distinct from the ring current, which itself varied between V1 and V2 observations) which are not well modelled by the uniform external field approximation used here.

The Voyager 1 observations suggest the presence of a large-scale current system, the exact geometry of which is as yet undetermined but is thought to involve $\sim 6 \times 10^6$ A of polar current flowing into Saturn's south pole. The unmodelled external field observed during the Voyager 2 encounter appears to be attributable to solar wind induced time variations in Saturn's magnetosphere. A better understanding of these external sources will probably be required before the Z_3 model can be improved, perhaps with the inclusion of (relatively small) non-axisymmetric terms. In its present form, however, the Z_3 model is consistent with the Pioneer 11, Voyager 1 and Voyager 2 magnetic field observations as well as the charged particle micro-absorption feature observed by the Voyager 2 CRS investigation[13] and identified with the satellite Tethys.

The Z_3 model leads to significantly enhanced polar surface field intensities on Saturn as shown in Fig. 1. Compare the surface field intensity of the Z_3 model as a function of latitude with that of an offset dipole model obtained by setting g_3^0 of the Z_3 model to zero, and that of a centred aligned dipole of moment $0.21\,G-R_S^3$. The maximum polar intensities in the north and south are ~0.84 and ~0.65 G, comparable with the Earth's ~0.7 G polar intensities. Note also that the equatorial surface field magnitude is reduced to ~0.18 G by the large g_3^0 term of the Z_3 model. The relative magnitude of the Z_3 model g_n^0 coefficients is compared in Fig. 2 with the relative magnitude of the Earth's axisymmetric g_n^0 terms[16]. Saturn's g_n^0 are larger in magnitude than those of the Earth.

Cowling's theorem[17] excludes the possibility of maintaining a steady state axisymmetric dynamo by fluid motions. It is possible, though improbable, that Saturn's highly axisymmetric field configuration is reflective of the decay phase of a magnetic field reversal[18]. More appealing is the suggestion that the dynamo itself is not axisymmetric[1] but only outwardly appears as such. If what we observe at Saturn is but the axisymmetric part of a complex Earth or Jupiter-like dynamo, the magnitude of Saturn's g_n^0 terms may be the only available observable relevant to Saturn's dynamo. The differential rotation of the metallic conducting shell above Saturn's dynamo in Stevenson's model[1] leads to an increase in the axisymmetric toroidal field deep within Saturn's interior. Some form of flux expulsion must inevitably occur to relieve the ever-increasing magnetic pressure. Could the process of flux expulsion result in a relatively short-lived and localized magnetic field anomaly unobserved by more distant spacecraft but sufficient to modulate Saturn's radio emission[19]? The lack of any detectable departure from axial symmetry remains the most enigmatic aspect of Saturn's unique magnetic field.

We thank our Voyager colleagues and our colleagues at the NASA Goddard Space Flight Center for useful discussions, also R. Thompson, F. Hunsaker, L. White, and the data processing and technical support staff at GSFC for their assistance.

Macroscopic evidence of molecular chirality in columnar mesophases

Jacques Malthête & Jean Jacques

Laboratoire de Chimie des Interactions Moléculaires, Collège de France, 11 place Marcelin Berthelot, 75231 Paris Cedex 05, France

Nguyen Huu Tinh & Christian Destrade

Centre de Recherche Paul-Pascal, Domaine Universitaire,
33405 Talence Cedex, France

Besides the classical liquid crystals observed with rod-like molecules (nematic and smectic mesophases) and plastic crystals obtained in the case of globular compounds, two new classes of thermotropic mesophases consisting of two-dimensional aromatic flat molecules have been investigated[1–3]: D columnar mesophases (columns of disk-like molecules in regular two-dimensional periodic array) and N_D nematic mesophase (disk-like molecules parallel to an average plane). We report here two examples of molecular chirality directly observable in D mesophases of a resolved disk-like compound.

Some hexasubstituted benzene[1], triphenylene[4–10], truxene[11–14] or anthraquinone[15,16] derivatives (Fig. 1) exhibit highly viscous and birefringent mesophases between the solid state and the isotropic liquid, which correspond to a columnar arrangement of diskoid molecules.

These columnar structures, denoted D in Fig. 2*a* legend, differ from one another by the symmetry group of the two-dimensional lattice and by the stacking, regular or not, of disk-like molecules in the columns[2]: hexagonal two-dimensional lattices (Fig. 2*b*) with order (D_{ho}) or disorder (D_{hd}) of the molecules in each column, rectangular two-dimensional lattice (Fig. 2*c*) with disorder of the molecules in each column (D_{rd}). The columns can be upright or tilted with respect to the molecular reference plane. A single example of strongly tilted columnar phase (D_t) has been observed (tilt angle ~55°)[9].

Fig. 1 Mesogenic disk-like cores.

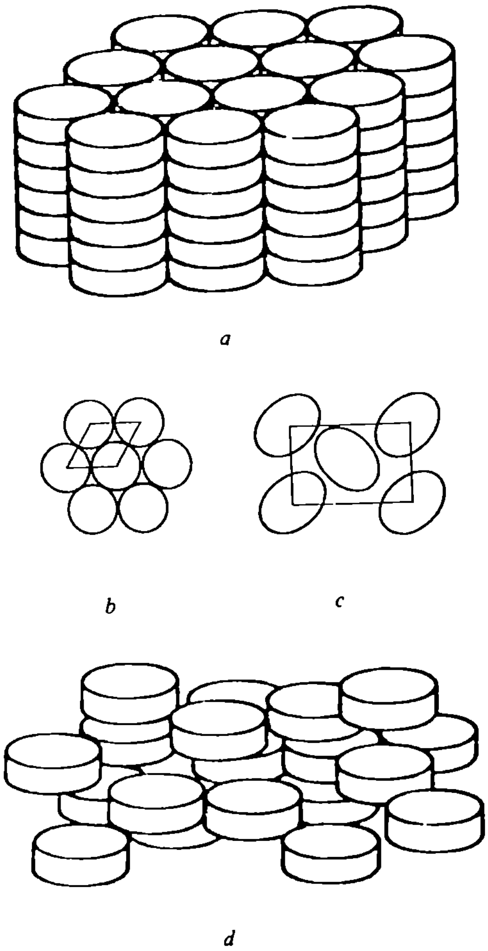

Fig. 2 *a*, Structure of columnar phase (with ordered disks). Schematic representation of hexagonal (*b*) and rectangular (*c*) phase lattices. D_{rd} phases are generally of the Pgg symmetry[17], but one example of Pmg symmetry has been described[15,16]. *d*, Structure of N_D nematic phase. The nematic nature of this phase has been checked by X-ray diffraction measurements[9].

A fluid phase (N_D) with optical schlieren texture, in any point similar to the classical nematic one, forms the second class of mesophases exhibited by disk-like compounds. This N_D nematic phase, in which the only order is a parallelism between flat cores (Fig. 2*d*), is observed with several hexa (*p*-alkyl or alkoxy) benzoyloxytriphenylenes[7–10] or truxenes[14] and with some hexaalkanoyloxytruxenes[11–13]. The chiral variant, cholesteric (N_D^*)[18,19], is obtained with optically active diskoid molecules.

We have recently described the two mesogenic enantiomers of the hexasubstituted triphenylene (*I*)[18]. Our first observations of the two successive thermotropic columnar mesophases of (+) or (−) (*I*) mounted between two glass slides and viewed under a polarizing microscope did not reveal any chirality in the medium. Nevertheless, we have shown that these substances could easily twist the N_D nematic phase of some hexabenzoyloxytriphenylenes as might be expected. Furthermore, we recently reported the existence of a N_D^* cholesteric phase for a pure disk-like compound[19].

The large analogy between columnar and smectic phases had given us an inkling of the existence of a twisting induced by

The two columnar phases of (*I*) were first identified with D_{rd} and D_{hd} owing to their textures and the miscibility of the low-temperature mesophase with some D_{rd} phases of hexaalkanoyloxytriphenylenes. But recent X-ray diffraction results on one enantiomer point out that the high-temperature columnar phase is, in fact, another rectangular phase with different symmetry. Pending more refined X-ray diffraction measurements we shall name the high temperature phase: D_{r1} and the low temperature one: D_{r2} (A. M. Levelut provided these preliminary data). (+)-(*I*) and (−)-(*I*) were purified by thin-layer chromatography on silica gel (using 10% acetone/hexane mixture as eluant) and recrystallized from ethanol/ether mixture. (+)-(*I*): $[\alpha]^{25}_{278} = +12.4°$ (c, 1 in chloroform) (Found: C, 74.70; H, 9.71; $C_{78}H_{120}O_{12}$ requires C, 74.96; H, 9.68). (−)-(*I*): $[\alpha]^{25}_{278} = -11.6°$ (c, 1 in chloroform) (Found: C, 74.81; H, 9.84; $C_{78}H_{120}O_{12}$ requires C, 74.96; H, 9.68). IR (neat) 1,770; 1,515; 1,255; 1,200; 1,125; 920 cm^{-1}. ^1H NMR ($CDCl_3$)δ 0.9 (*s*, 18 H), 1.1 (*d*, $J = 6.3$ Hz, 18 H), 1.35 (*s*, 60 H), 2.1 (*m*, 6 H), 2.5 (*m*, 12 H), 8.2 (*s*, 6 H).

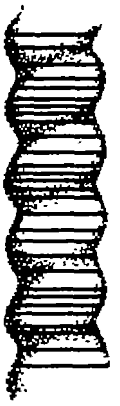

Fig. 4 Spiral column (with disordered optically active molecules).

optically active molecules in a tilted columnar phase (D_t) [18], as was the case with biaxial tilted smectics (S_C, S_F, S_I) composed of rod-like molecules[20,21].

The two columnar phases of (*I*) were first described as upright D_{rd} and D_{hd} phases[18]; consequently the absence of twisting with optically active solute molecules looked 'normal'. But some recent optical observations—in the case, for example, of (*I*) with R = *n*-alkanoyl chain (P. Oswald, personal communication)—seem to favour a slight tilt of the columns, and so we have made new observations on free droplets.

A careful re-examination of the two columnar mesophases of compound (*I*) allowed us to observe an evident chirality and to prove the existence of new chiral mesophases.

The transition temperatures (°C) of (+) or (−)-(*I*) are:

K 59 D_{r2} 64.5 D_{r1} 97.5 I (K, crystal; I, isotropic liquid).

The racemic mixture (±)-(*I*) melts at 47.5 °C and the isotropic phase appears at 95.5 °C.

On cooling isotropic free droplets, one can see—between crossed polarizers—near 96 °C, a fan-shaped texture consisting of only one type of pairs with 'opposite points'. Both enantiomers exhibit similar non-superposable figures, each one being the reflection image of the other (Fig. 3a_1, b_1). On further cooling, near the $D_{r1} \rightarrow D_{r2}$ transition, a spiralization of the medium is evident: some spirals are generated around the pairs of opposite points as shown in Fig. 3$a_{1,2}$, $b_{1,2}$. On heating immediately after the spiralization takes place, the effect remains up to the clarification point, but if the temperature is maintained for a few minutes a progressive change in the spiral figures can be seen. Once more we observe two antipodal figures (Fig. 3a_2, b_2). In addition the spirals reveal a periodicity of the oily streaks (note that, in all the figures, 'opposite points' and spirals are visible—but less clearly—between uncrossed polarizers).

In the case of an equimolecular mixture of (+)-(*I*) and (−)-(*I*), we observe, as expected, non-chiral figures resembling concentric rings (D_{r2}) or face-to-face 'opposite points' (D_{r1}) (Fig. 3*c*). We have noticed that many achiral disordered columnar phases ((*I*) with R = *n*-alkanoyl chain) consist of a statistical mixture of right- or left-handed spirals or opposite points in addition to some perfect achiral figures.

3-Methylnonanoic acids (R)-(+)-(*IV*) and (S)-(−)-(*IV*) have been prepared by a convenient adaptation of a procedure described by Prout *et al.*[22] from (S)-(+) and (R)-(−)-2-octanols (via the *p*-toluenesulphonates). Hexaesters (+)-(*I*) and (−)-(*I*) were obtained by interaction of the 3-methylnonanoyl chlorides (respectively from (R)-(+)-(*IV*) and (S)-(−)-(*IV*) with 2, 3, 6, 7, 10, 11-hexahydroxytriphenylene (*II*) prepared by heating the corresponding hexamethoxy derivative (*III*) with pyridine hydrochloride[23]. Compound (*III*) was prepared by treating veratrole with *p*-chloranil in sulphuric acid[24].

We have presented the first evidence of two rectangular columnar mesophases which form examples of a directly observable molecular chirality. Nevertheless, the chiral molecular packing in these media raises several questions:

- Why are the enantiomorphic figures clearly visible only on free droplets?
- Is each column chiral—as, for instance, one of the enantiomorphic spiral columns of St Peter's high altar in the Vatican City (Fig. 4)?
- Or is this phenomenon connected to a peculiar chiral packing on the surface of the mesomorphic droplet?

We are now carrying out optical studies and X-ray diffraction measurements to understand more closely the structure of these two mesophases.

We thank Dr J. Prost for cooperation, Dr A. M. Levelut and Professor Y. Bouligand for interest, discussions and some preliminary X-ray measurements.

Electron density images from imperfect data by iterative entropy maximization

Douglas M. Collins

Department of Chemistry, Texas A & M University,
College Station, Texas 77843, USA

Information theory provides a uniquely powerful apparatus for reconstructing an image from imperfect data in its dual space. An iterative procedure based on constrained entropy maximization is presented here for reconstruction of electron density from imperfect single-crystal X-ray diffraction data. In the ideal situation, continuous electron density, its periodicity given by the lattice, is the Fourier transform of an infinite set of structure factors whose squared moduli are observables. An ideal electron density is unattainable from experiment because of the common experimental inadequacies of incomplete and noisy data discussed by Gull and Daniell[1]. These inadequacies are partially overcome in the present procedure which yields true super-resolution and is economical even for protein crystal structures as illustrated.

Although Gull and Daniell[1] focused on radioastronomical applications, their maximum entropy solution for a best map of radio intensity from experimental data is quite general, and its formalism is appropriate to the X-ray crystallographic problem. Nevertheless, the formalism is unsatisfactory for many crystallographic applications on two counts. First, convergence properties are not characterized and appear to be undesirable as recourse to partial sums was required for convergence in the reported application[1]. Second, the formalism fails in the absence of noise; this is a common difficulty with many spectral analyses based on entropy maximization[2]. It could be argued that artificial introduction of noise is possible in the presumably few applications for which the naturally occurring noise level is inadequate. However unlikely, such a state of affairs in experiments carefully designed to minimize or offset natural noise constitutes a dilemma to be avoided.

A formalism, designed from the outset to result in an iterative procedure, for a maximum-entropy mapping of electron density can be readily composed with the aid of an approximation for the natural logarithm. We assume that the corresponding inexactness for the most part becomes immaterial on iteration as in any successive approximation procedure. It also will be assumed that the density functions and the experimental data are discrete samplings on regular grids appropriate to discrete Fourier transform algebra[3].

Consider that there is a positive definite trial electron density τ obtained from the transform of experimental structure factors $\hat{F}$ (experimental modulus, model-based phase); the scale of $\hat{F}$ is set to make $\hat{F}_{\mathbf{k}=0}$ equal the number of electrons in a unit cell. Within the range of observations it is desired that F the transform of ρ differs from $\hat{F}$ as little as possible subject to maximization of the entropy which measures the difference between ρ and τ, ρ constrained to be positive definite. After the pattern of Gull and Daniell[1] maximize

$$Q(\lambda) = -\sum_{\mathbf{x}} \rho'_{\mathbf{x}} \ln[\rho'_{\mathbf{x}}/\tau'_{\mathbf{x}}] - \frac{\lambda}{2} \sum_{\mathbf{k}\in K} |F_{\mathbf{k}} - \hat{F}_{\mathbf{k}}|^2/\sigma^2_{\mathbf{k}}$$

by setting

$$\partial Q(\lambda)/\partial \rho_{\mathbf{x}} = 0$$

where the sum over $\mathbf{x}$ includes a complete unit cell, the entropy formula[4] uses $\rho' = \rho/\sum \rho_{\mathbf{x}}$ and $\tau' = \tau/\sum \tau_{\mathbf{x}}$, λ is a disposable constant to be evaluated, K denotes the set of reciprocal lattice points for which there are useful observations, and σ is the standard deviation of $\hat{F}$. Evidently

$$-\ln \rho_{\mathbf{x}} + \ln \tau_{\mathbf{x}} + A + \hat{F}_{\delta}\lambda \sum_{\mathbf{k}\in K} \frac{1}{\sigma^2_{\mathbf{k}}} (\hat{F}_{\mathbf{k}} - F_{\mathbf{k}}) \exp\{-2\pi i \mathbf{k}\cdot\mathbf{x}\} = 0 \quad (1)$$

for which the relationship $\hat{F}_0 = \sum(\text{volume/grid point})\rho_{\mathbf{x}}$ has been used, it is assumed that $-\mathbf{k}\in K\ \forall \mathbf{k}\in K$, and A is given by

$$A = (\sum \rho_{\mathbf{x}})^{-1} \sum \rho_{\mathbf{x}} \ln[\rho_{\mathbf{x}}/\tau_{\mathbf{x}}]$$

If as desired the agreement between $\hat{F}$ and F is good, then A which measures the scale disparity between ρ and τ is small. Neglect of A and rearrangement of equation (1) result in

$$\rho_{\mathbf{x}} = \exp\left[\ln \tau_{\mathbf{x}} + \hat{F}_0\lambda \sum_{\mathbf{k}\in K} \frac{1}{\sigma^2_{\mathbf{k}}} (\hat{F}_{\mathbf{k}} - F_{\mathbf{k}}) \exp\{-2\pi i \mathbf{k}\cdot\mathbf{x}\}\right] \quad (2)$$

which forms the basis for the reconstruction procedure presented here. Note that equation (2) certainly satisfies one of the two earlier mentioned problems of convergence and (possibly) noise-free data. Disappearance of the latter problem is trivially evident, for if the modelled density should ever transform to $F_{\mathbf{k}} = \hat{F}_{\mathbf{k}}$, $\forall \mathbf{k}\in K$, then $\rho = \tau$ and cannot be changed by use of equation (2). Although neglect of A may bias the entropy term, a formalism results which, as desired, does not fail in the absence of noise. On the other hand, use of $A = 0$ means the convergence question must await an empirical answer as initially provided in the illustration.

Equation (2) may be rearranged to yield

$$\ln[\rho_{\mathbf{x}}/\tau_{\mathbf{x}}] = \hat{F}_0\lambda \sum_{\mathbf{k}\in K} \frac{1}{\sigma^2_{\mathbf{k}}} (\hat{F}_{\mathbf{k}} - F_{\mathbf{k}}) \exp\{-2\pi i \mathbf{k}\cdot\mathbf{x}\}$$

For good agreement of ρ and τ the logarithm may be approximated as

$$\ln x \approx x - 1$$

to give

$$(\rho_{\mathbf{x}} - \tau_{\mathbf{x}}) = \tau_{\mathbf{x}}\hat{F}_0\lambda \sum_{\mathbf{k}\in K} \frac{1}{\sigma^2_{\mathbf{k}}} (\hat{F}_{\mathbf{k}} - F_{\mathbf{k}}) \exp\{-2\pi i \mathbf{k}\cdot\mathbf{x}\}$$

which permits a formal estimation of λ at $\tau_{\max}$. Correspondence with standard crystallographic difference map formalism[5] implies for λ the evaluation

$$\lambda = (V\tau_{\max}\hat{F}_0)^{-1} \left(\frac{1}{n_K} \sum_{\mathbf{k}\in K} \frac{1}{\sigma^2_{\mathbf{k}}}\right)^{-1} (2 - \delta_{\bar{1}})$$

where V is the volume of a unit cell, n_K is the number of terms in the sum, and $\delta_{\bar{1}} = 1$ or 0 according to the presence or absence of a centre of symmetry. For constant errors, $\lambda = (V\tau_{\max}\hat{F}_0)^{-1}\sigma^2(2 - \delta_{\bar{1}})$. It follows that the standard crystallographic difference synthesis may be interpreted as an approximate difference between unit-weighted maximum-entropy representations of experimental and modelled electron densities.

Deterministic interpretation of the logarithm of equation (2) suggests the form

$$\ln \rho_{\mathbf{x}} = \ln \tau_{\mathbf{x}} + \text{corrective terms}$$

or

$$\ln(\rho_{\mathbf{x}}/\tau_{\mathbf{x}}) = \text{corrective terms}$$

For a formal difference of <10% between τ and ρ, the left-hand side may be approximated within 0.1% as

$$\ln(\rho/\tau) = (\rho - \tau)/\tfrac{1}{2}(\rho + \tau) \approx \Delta\rho/\rho$$

Evidently this would be an accurate deterministic form for the

Table 1 The course of reconstruction

	At the start	After four iterations

corrective terms. With λ evaluated at $\tau_{\max}$, the maximum entropy solution for corrective terms as given in equation (2) differs from the deterministic form only as the values for ρ move down from their highest levels. This fortuitously corresponds with the experimental situation in which the lowest levels of a density function are usually rather less significant than the highest levels. Relative to accurate deterministic corrections, the maximum-entropy corrections down-weight the significance of the lowest density levels through absence of the ρ^{-1} dependence. Moreover, because the highest density levels contribute most to the value for F, and because the maximum entropy corrections place functional emphasis on correcting the highest density levels, it is expected that repeated application of equation (2) quite generally will constitute a stable, convergent, iterative reconstruction of electron density. Although in the presence of error the resulting density may never be better than an asymptotic approximant, it will be positive definite, well behaved, and in good agreement with the observations by the criterion of a constrained maximum of configurational entropy.

'Super-resolution' is a term used[1,2] to denote the fact that maximum-entropy methods can yield functions of resolution higher than that which corresponds to the band limits of the data. The term is sometimes used to indicate that the presence of noise in a set of data can lead to apparent but improperly high resolution. Super-resolution of the proper sort is highly desirable and can be understood to arise in the present case through imposition of a (perfectly general) model for electron density. While the maximum-entropy formalism yields a result which is maximally non-committal with regard to missing or unavailable data[6,7], it does require an exponential representation for the density function. Because the sampling of the density may be made arbitrarily dense, the exponential representation corresponds to a function which is not only positive definite and well behaved, but also continuous and consequently possessed of an infinite transform with unlimited resolution. There is no general way to know how well the implied transform samples for $\mathbf{k} \notin K$ agree with the unavailable observations or even that they agree at all. But in crystallographic application maximum-entropy formalisms can lead to density maps at more than twice the resolution expected for straightforward Fourier synthesis of structure factors[8]. As we now show, iterative reconstruction based on equation (2) does in fact produce real super-resolution.

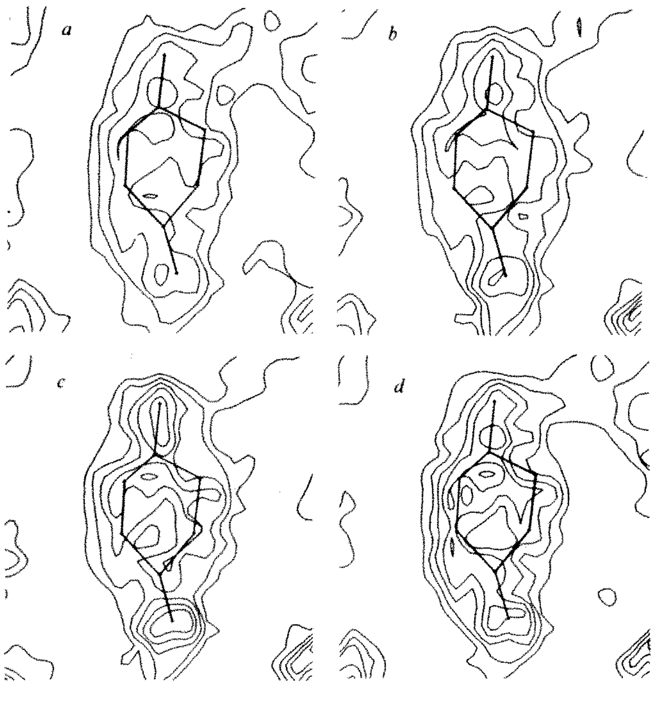

Fig. 1 *a*, Tyrosine-11 based on 2.0 Å data and isomorphous replacement phases. *b*, Tyrosine-11 based on 2.0 Å data and least-squares phases. *c*, Tyrosine-11 based on 1.5 Å data and least-squares phases. *d*, Tyrosine-11 in a maximum entropy reconstruction iteratively developed from the data and phases used in *a*.

The rubredoxin of *Clostridium pasteurianum* has been studied in single-crystal X-ray diffraction experiments and its noncentrosymmetric structure reported[9] at a resolution of 1.5 Å (minimum interplanar spacing). A structure model was fitted to the 1.5 Å experimental data by least squares and the structure-factor phases computed from this model, the experimental structure-factor moduli, and the atom coordinates of the model are all given in the structure report[9]. Phases which had been determined by isomorphous replacement methods at 2.0 Å resolution were provided by Dr Sayre with permission from Professor Jensen. The reconstruction procedure used for the present illustration may be outlined as follows. (1) Compute an electron density τ using $\hat{F}$ the experimental structure moduli and phases from isomorphous replacement, all at 2.0 Å resolution, and to ensure a positive definite density at the start replace τ by the larger of $(\tau, \tau_{\max}/100)$ for each position $\mathbf{x}$. Compute and file $\ln \tau$ and the transform of (modified) τ as initial F. (2) Computation of equation (2) with the phase of F assigned to $\hat{F}$ gives ρ whose transform is a new F and logarithm is a new $\ln \tau$. (3) Scale $|F|$ so it is on the same scale as $|\hat{F}|$ and compute

$$R = \sum_{\mathbf{k}\in K} ||\hat{F}_{\mathbf{k}}| - |F_{\mathbf{k}}|| / \sum_{\mathbf{k}\in K} |\hat{F}_{\mathbf{k}}|$$

(4) Repeat steps (2) and (3) until the improvement in R is judged to be not significant.

Although 1.5 Å data are available for rubredoxin, only the 2.0 Å subset together with initial isomorphous-replacement phases were used in the reconstruction. This allows for demonstration of super-resolution by comparison of the reconstructed density function with a reference density using about twice as much data. The reference density was obtained by standard Fourier synthesis of a complete 1.5 Å structure-factor set obtained as experimental moduli and phases calculated from the refined atomic model; these calculated phases are considered to be correct for this illustration.

The course of the calculation through four iterations is summarized in Table 1. Each iteration is based on a forward and reverse Fourier transformation[10] of samples on a grid of 64 points per cell edge. Computing time for each complete iteration was ~30% more than required for the Fourier syntheses alone. For the 2,812 unique data used, the average magnitude of difference between the phases from the maximum entropy method α_{MEM} and the phases from the atomic model, the so-called least-squares phases α_{LS}, is given in Table 1. A companion entry gives the average magnitude of difference between α_{MEM} and the phases from isomorphous replacement α_{IR}. These average phase deviations taken together show that the maximum entropy method yields a result which in some sense concerning phases lies between the sets from isomorphous replacement and least-squares refinement. The value for $R = \sum ||\hat{F}| - |F|| / \sum |\hat{F}|$ is amenable to more definite interpretation. A first significance of R is as a criterion of convergence for the reconstruction procedure. An analytical discussion of this point is lacking but it is easy to see that the procedure will stop if and only if $R = 0.0$. Yet if R stops changing between iterations, then clearly in some average sense no further desirable change is occurring. A second use for R or its value at convergence is as a preliminary indicator of global error in a data set. Because the exponential model for electron density is perfectly general, error-free data ideally should yield $R = 0.0$ at the conclusion of a maximum-entropy reconstruction. Of course, data are not error-free and random data errors correspond to an uncorrelated, necessarily zero-mean process which is not representable by an exponential model. The maximum entropy procedure may, nevertheless, offset some error effects, but in unpredictable ways because the exponential representation of density plus error destroys the additive relationship. With reservation in this regard and also concerning the possibility of false entropy maxima, it seems that the asymptotic value of R should approximate $\sum|\varepsilon|/\sum|\hat{F}|$, ε being the true experimental error in $|F|$.

Quality of image is demonstrated in Fig. 1 by comparison of different representations of the tyrosine-11 residue of rubredoxin[9]. Tyrosine-11 was chosen on the joint grounds of its planarity and previous use as an example[9,11]. Figure 1*a–d* shows interpolated sections of density maps in the least-squares plane of the reported coordinates for atoms in the planar tyrosine group. Contour levels begin at 0.0 and increase in steps of 0.30 electrons $Å^{-3}$; the line segment ends correspond to reported atomic positions. Figure 1*a* is based on 2.0 Å data with phases from isomorphous replacement and represents the starting point for all further structure description and refinement. Figure 1*b*, *c* are based on the least-squares phases calculated from the atomic model. Although the reported atomic model and associated phases are being used here as a kind of standard, note that in the original report they were considered subject to improvement. Clearly, Fig. 1*b* which is based on 2.0 Å data and least-squares phases gives a better representation of tyrosine than does Fig. 1*a*. Figure 1*c* which is based on least-squares phases and the complete 1.5 Å data set is even better and of obviously higher resolution. The maximum-entropy reconstruction is given in Fig. 1*d* which is more similar to Fig. 1*c* than to the others. In fact one could reasonably argue from their appearance that Fig. 1*d*, if anything, is of higher resolution than Fig. 1*c*. Clearly, the maximum entropy reconstruction based on only 2.0 Å data and isomorphous–replacement phases shows real super-resolution as it is of obviously greater true resolution than the classical representation of the same data given in Fig. 1*a*.

Maximum-entropy methods for image reconstruction potentially yield the best image model derivable from the available data[2]. This does not refer to a best image model in an absolute sense, but in the sense of being the model least likely to need correction on measurement and consideration of additional data[2]. While the virtues of maximum entropy analysis are claimed for the present procedure, the approximations used mean that its details could be improved on. In connection with the rubredoxin illustration, note that individual standard errors for structure moduli were not used and the default unit values are not commensurate with optimum results from the calculations. Even so, in contrast to other types of image enhancement[8,12], the present procedure seems to be exceptionally stable and requires no special adaptation for dominating atoms or groups as, for example, the iron–sulphur group of rubredoxin. While no evidence has been developed in specification of a radius of convergence, it seems that the outlined procedure is applicable without further modification in every case for which there are structure moduli and corresponding initial phases of the quality normally attained by isomorphous replacement methods.

I thank J. Skilling for help with formulation of the entropy expression. This work has been supported in part by the Robert A. Welch Foundation through grant A-742 and by the Research Corporation through a Cottrell Research Grant.

Structure of the Red Sea at 20° N from gravity data and its implication for continental margins

C. Brown* & R. W. Girdler

School of Physics, The University, Newcastle upon Tyne
NE1 7RU, UK

Recent gravity data have enabled a gravity profile extending 1,500 km over Nubia, the Red Sea and Arabia to be compiled. Using a modal value of −48 mGal for the Bouguer anomaly over Africa away from regions of rifting we have determined the way in which the lithosphere thins and breaks to form the Red Sea. We find that nearly the whole of the Red Sea from coast to coast is probably underlain by oceanic crust and the regions of thinning extend for ~120 km landwards of the Nubian coast and 180 km landwards of the Arabian coast. This implies that for continental margins similar to those of the Red Sea, the vast thicknesses of sediments might be underlain by early oceanic lithosphere rather than by thinned and downfaulted continental lithosphere.

The Red Sea is a critical region for studying the breakup of the continents, the evolution of continental margins and new oceanic crust. The presence of large positive Bouguer gravity anomalies over the deep axial trough suggested that the trough might be underlain by dense oceanic crust[1]. This was confirmed in the 1960s when high seismic velocities and large magnetic anomalies were found[2]. The magnetic anomalies were interpreted in terms of seafloor spreading[3] and a model constructed in which the deep axial trough was underlain by oceanic crust formed over the past few million years and the main trough and shelves were underlain by downfaulted shield rocks covered by large thicknesses of sediments[4,5]. In 1970 McKenzie *et al.*[6] applied plate tectonics and fitted the remarkably parallel shorelines (previously noticed by Wegener). This stimulated much new work on the nature of the crust underlying the vast thicknesses of sediments to the sides of the axial trough. In particular, magnetic surveys showed remarkable lineations and the suggestion was made that the Red Sea may have formed in at least two stages of seafloor spreading[7]. Further studies[8] showed magnetic lineations over the margins of the Red Sea to be widespread. Recently, a very detailed aeromagnetic survey (R. Horn, personal communication) has been carried out between Sudan and Arabia on behalf of the Red Sea Commision. This shows extensive lineations with remarkable symmetry. The magnetic anomalies thus suggest the presence of oceanic crust beneath the sediments and extending approximately to the coasts at least in the southern two thirds of the Red Sea. This is also supported by the interpretation of the gravity anomalies.

Gravity data from a recent geotraverse across northern Africa[9] enable a long profile to be constructed across the Red Sea and its neighbouring Nubian and Arabian plates. The location of the profile is shown in Fig. 1. The coordinates of the stations in Nubia and Arabia were projected onto a line with azimuth N56° passing through Port Sudan. For Nubia, 32 stations obtained on the geotraverse provided simple Bouguer anomalies and heights at an average spacing of 16 km. For the Red Sea, Bouguer anomalies and depths on a N56° line from Port Sudan to Jeddah were obtained from charts with contour intervals 10 mGal and 100 m respectively[10]. For Arabia, Bouguer anomalies and heights for 21 stations[11] eastwards from the Red Sea Arabian coast at an average spacing of 15 km were used. The complete profile (Fig. 2*a*) shows that the whole of the Red Sea from coast to coast is associated with positive

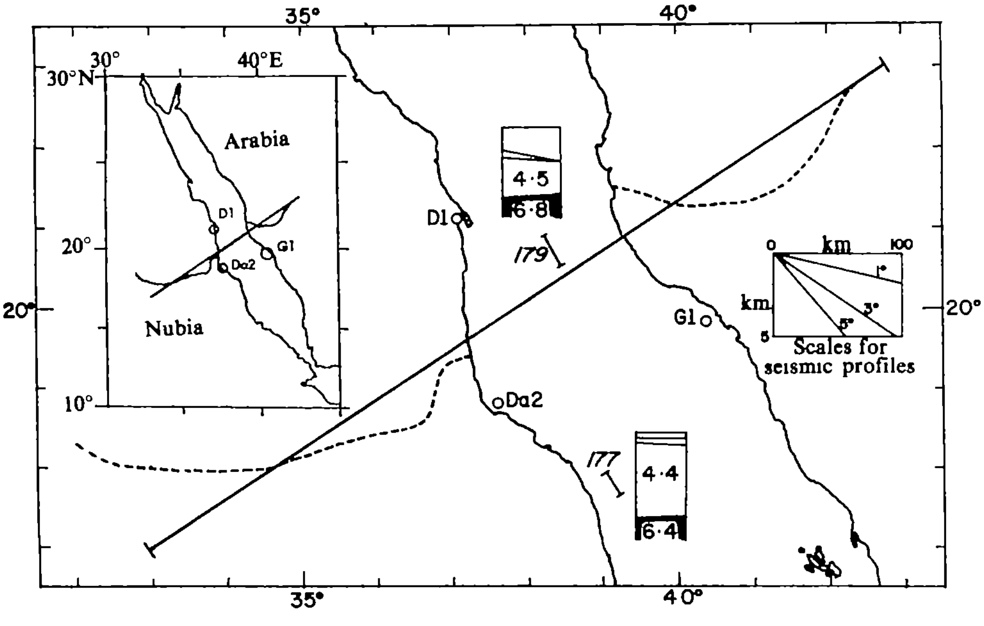

Fig. 1 The location of the profile and its projection on to the line N56°. The locations of the boreholes Dungunab-1 (D-1), Durwara-2 (Da-2) and Ghawwas-1 (G-1) and seismic refraction lines 177 and 179 are also shown.

Bouguer anomalies which reach a maximum of more than +100 mGal. Landwards from the coasts the anomalies become negative reaching values of −50 mGal on the Nubian side and −100 mGal on the Arabian side.

To interpret the profile we need to make assumptions concerning the thickness and structure of the lithosphere away from the regions of rifting and to estimate the regional gravity anomaly. For the continental US, isostatic response data[12] seem to be incompatible with density anomalies below ~80 km but in Canada observations of the wavelength and amplitude of bending in the vicinity of supercrustal loading[13] give estimates of ~110 km for lithospheric thickness. For unrifted Africa, the simple assumption is made that the lithosphere is 100 km thick and is associated with a Bouguer anomaly of −48 mGal derived from a statistical study of 1°×1° means[14]. The structure of the African lithosphere based on seismic studies[15] with the velocities converted to densities using the Nafe–Drake curve[16] is shown in Fig. 2*a* and the more detailed structure of the crustal part in Fig. 2*b*.

For the continental part of the profile it is necessary to compute geological corrections for the light volcanics and sediments near Harrat Rahat and Harrat al Kishb at ~22.5° N, 41°E. A uniform specific gravity (SG) of 2.3 was assumed with the volcanic pile underlain by PreCambrian basement at sea level. It is also necessary to correct for the light sediments on the Nubian and Arabian coastal plains. These were assumed to have a uniform SG of 2.2 with thicknesses taken from the Tectonic Map of Africa[17].

For the Red Sea, there are three boreholes in the neighbourhood of the profile[19], two on the Nubian side and one on the Arabian side (Fig. 1). All are close to the coasts. On the west side, the borehole to the north, at 21.10° N, 37.10° E (Dungunab-1) has 1,563 m of sediment and the borehole to the south at 18.81° N, 37.64° E (Durwara-2) has 4,152 m of sediment. Both then penetrated basalt. The borehole on the east side at 19.84° N, 40.37° E (Ghawwas-1) has a sediment thickness >3,446 m. There are also two reversed seismic refraction profiles[2] which constrain the velocity structure to the top of the oceanic layer 3 in the main trough (line 177) and axial trough (line 179). The velocities were converted to specific gravities using the Nafe–Drake curve[16] giving values of 2.00 (equivalent to 2.3 km s^{-1}) for the sediments, 2.45 (4.4 km s^{-1}) for the evaporites and 2.80 (6.45 km s^{-1}) for oceanic layer 3. The Mohorovičić discontinuity was not detected on these lines and a depth of 11 km was assumed. If it is assumed that isostatic compensation is complete at 100 km (the depth assumed for the base of the African lithosphere[14]), a simple calculation shows that the average specific gravity of the oceanic mantle beneath line 177 in the main trough is ~3.25. The details of the Red Sea structure used in the interpretation of the gravity profile are shown in Fig. 2*b*

With these constraints the lithospheric structure was adjusted until the Bouguer anomaly was fitted to within ±10 mGal over the whole length of the profile (Fig. 2*a*).

The resulting structure shows the following features from west to east: (1) As the western margin of the Red Sea is approached, the lithosphere begins to thin rapidly. (2) The continent–ocean boundary is only 7 km seaward of the Nubian coast at this latitude. (3) A crustal intrusive zone about 90 km wide exists beneath the centre of the Red Sea. Its top is at a depth of 4 km and it has a SG of 2.88 corresponding to the 6.76 km s^{-1} layer observed on seismic line 179. (4) The ocean–continent boundary coincides with the coastline on the Arabian side. (5) The region of lithospheric thinning has a slightly different form on the eastern side. (6) The 'normal' lithosphere is reached between 120 and 180 km from the coasts.

The model demonstrates that nearly all of the Red Sea at 20° N is underlain by oceanic crust but note that the exact demarcation of its boundaries depends critically on the specific gravities and thicknesses of the sediments and evaporites forming the marginal shelves.

A similar result has been obtained by Gettings[19] for a gravity survey of the Arabian margin between 16.3° N and 17.3° N, which includes the Tihamah Asir Coastal plain. Here, an extremely steep gradient (4–5 mGal km^{-1}) is observed at the Tihamah-shield boundary. Gettings interprets this as indicating the presence of oceanic crust beneath the Tihamah as well as beneath the Red Sea shelf.

Independent support for the presence of oceanic crust beneath the Red Sea shelves (apart from the magnetic lineations discussed earlier) comes from the fact that the whole of the Red Sea is a region of high heat flow[20]. It has been shown[21] that the heat flow values from boreholes on the Sudan coastal plain are considerably higher than would be expected from the radioactive heat production of granitic continental crust.

Although our results are based primarily on the gravity profile across the Red Sea, they are consistent with other geophysical data for this region.The conclusion that the whole of the Red Sea at 20° N, including the vast thicknesses of sediments on the shelves is underlain by oceanic crust agrees with results from the westernmost Gulf of Aden[22] where seismic reflection and gravity data require the ocean–continent boundary to be between the 183 m contour and the coast. In these regions, attenuation of the lithosphere, such as there is, seems to be landward of the coasts. Other passive continental margins similar to those of the Red Sea and Gulf of Aden might have

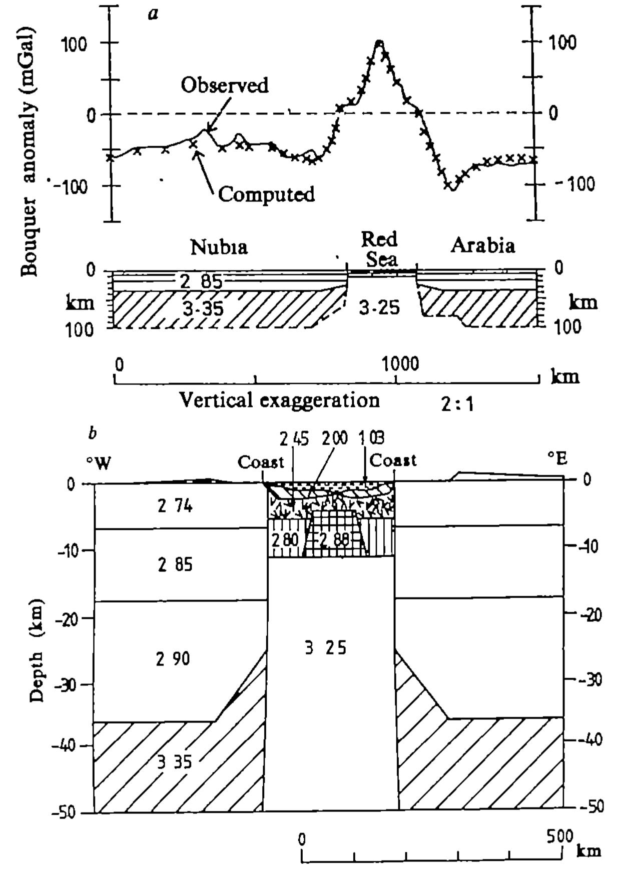

Fig. 2 *a*, The Bouguer gravity anomaly profile with the lithospheric structure used to fit the observed values. Details of the crustal structure of the Red Sea and the neighbouring continental lithosphere are shown in Fig. 2*b*. The positive anomaly over the Red Sea is due to the intrusive zone penetrating upper parts of the lithosphere giving a positive density contrast. The sharp boundaries between the anomalous mantle beneath the Red Sea and the normal mantle beneath the continents have been introduced to facilitate the gravity computations and should not be construed to represent an abrupt transition between geologically distinct regions in the mantle. *b*, Details of the structure of the crust and upper mantle used in the interpretation of the gravity profile shown in *a*. The attraction of each layer has been computed using a reduced specific gravity $\rho' = \rho - 2.67$ where ρ takes the following values: 2.00 (sediments); 2.45 (evaporites); 2.80 (oceanic layer 3); 2.88 (crustal intrusion); 3.25 (anomalous mantle) for the Red Sea and 2.74 (upper crust), 2.85 (middle crust); 2.90 (lower crust), 3.35 (normal mantle) for the continental lithosphere. The attraction of the mantle layers have been computed to a depth of 100 km.

oceanic crust underlying their shelves and we suggest that theories for the evolution of such 'continental margins' should consider this possibility.

We thank Dr Peter Styles for helpful comments and C.B. is indebted to the NERC for a research studentship.

Significance of $^{87}Sr/^{86}Sr$ ratios in the Merensky cyclic unit of the Bushveld Complex

F. J. Kruger & J. S. Marsh

Department of Geology, Rhodes University,
Grahamstown, 6140 South Africa

In a number of mafic layered intrusions, layers with platinum group element (PGE) mineralization coincide with breaks in cumulus mineral composition and isotopic variation trends through the layered sequence[1,2]. For example, in the Bushveld Complex in South Africa, abrupt increases in initial $^{87}Sr/^{86}Sr$ ratios occur at the UG-2 and Merensky pegmatoid (or 'reef') horizons, both of which are exploited for PGEs. We report here the results of a detailed Sr-isotope study across the Merensky unit and its immediate foot- and hangingwall-rocks which, when considered together with new ideas on processes operating in magma chambers[3–5], suggest that magma mixing and post-cumulus infiltration of liquids displaced from below were important during crystallization of the Merensky pegmatoid.

In the Bushveld Complex the PGE-bearing Merensky pegmatoid is part of the Merensky cyclic unit which occurs at the base of the main zone (subdivision after Willemse[6]—Fig. 1). Above the Merensky unit lies the lithologically similar Bastard cyclic unit. Both these units consist of a basal layer of orthopyroxenite which grades upwards through mela- and leuconorite into anorthosites with sporadically developed poikilophitic orthopyroxene crystals ~5 cm across, known as 'mottled anorthosites'. Thin stringers of chromitite usually occur at the base of each unit. In the case of the Merensky unit a layer of pegmatoid consisting mainly of large orthopyroxene crystals with interstitial plagioclase occurs at the base—this is the PGE-bearing Merensky pegmatoid.

As part of a detailed study of the Merensky unit at Rustenburg Platinum Mines in the western lobe of the Bushveld Complex, we have determined $^{87}Sr/^{86}Sr$ ratios (Table 1) on a suite of whole rocks and plagioclase collected from these two cyclic units and the immediate footwall to the Merensky pegmatoid. The variation of initial Sr-isotope ratios with height (Fig. 1) indicates a step-like pattern which confirms, in general, the results of Hamilton[1].

Plagioclase separates from the Footwall unit and the Merensky pegmatoid and pyroxenite have a constant initial $^{87}Sr/^{86}Sr$ which, significantly, is identical to that for rocks from the same stratigraphic interval in the eastern lobe[1]. With height through the Merensky unit we find a dramatic increase in $^{87}Sr/^{86}Sr$ for both whole rocks and plagioclase. In a 60-m section through the overlying Bastard unit the initial ratios are more uniform, but not constant, between 0.70749 and 0.70803, which is within the range found by Hamilton for the main zone of the eastern lobe.

This pattern of initial $^{87}Sr/^{86}Sr$ ratio variation can help constrain processes occurring at this level during the crystallization of the Bushveld Complex. In general, two main models can be envisaged. First, the increase in $^{87}Sr/^{86}Sr$ through the Merensky cyclic unit and the high values (for mafic rocks) for main zone samples might reflect *in situ* contamination of the existing magma by its wall rocks. Alternatively, the main zone rocks might have crystallized from an influx of new magma (with

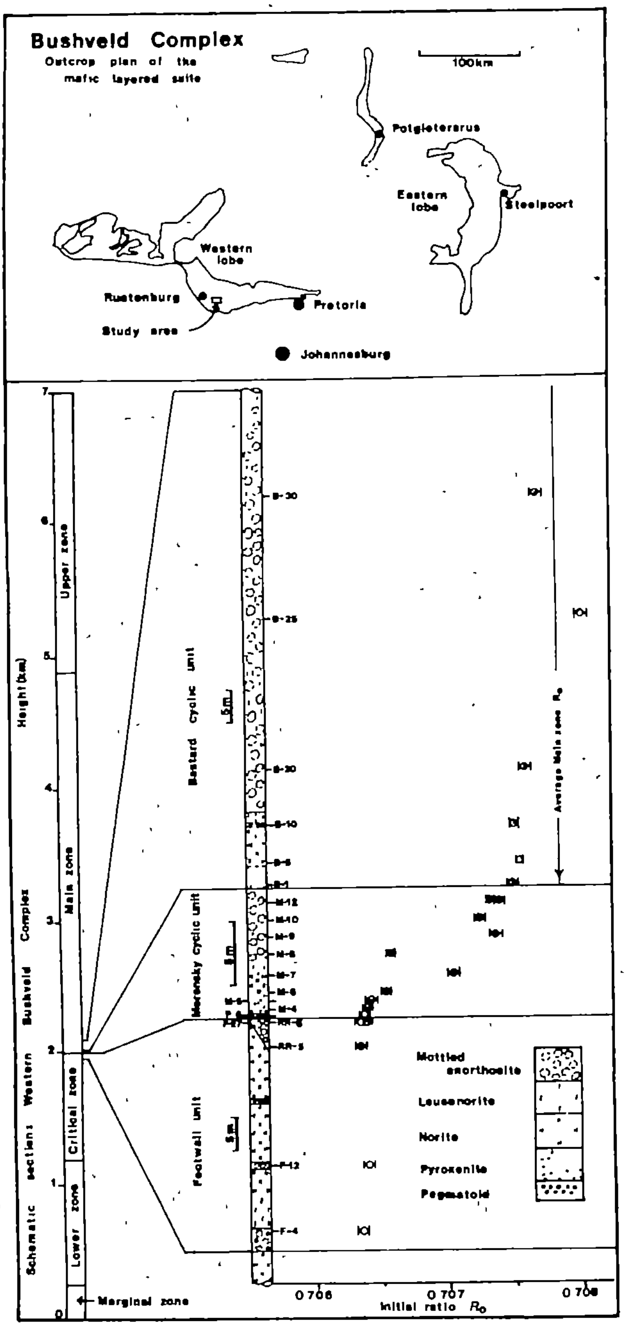

Fig. 1 Location map and stratigraphical positions for samples for which initial $^{87}Sr/^{86}Sr$ ratios have been determined. Note the differences in scale between the Merensky and Bastard and Footwall units. The average main zone initial $^{87}Sr/^{86}Sr$ (R_0) ratio is from ref. 1. O, Plagioclase; ●, whole rocks.

$^{87}Sr/^{86}Sr > 0.7075$) into the chamber and the Sr-isotope variation in the Merensky unit reflects the interaction of this new magma, or its crystallization products, with existing material in the magma chamber.

For the case of *in situ* contamination, magma with $^{87}Sr/^{86}Sr = 0.7064$ crystallized to produce the footwall sequence. At the start of accumulation of the Merensky unit, the existing magma became contaminated with more radiogenic Sr, presumably by mixing with partial melts generated in the roof and walls of the intrusion. The increasing $^{87}Sr/^{86}Sr$ ratio in the Merensky cyclic unit would therefore reflect progressive contamination of the magma and the increasing incorporation of more radiogenic Sr into cumulus minerals that build the cyclic unit. Contamination ceased at the level of the base of the Bastard cyclic unit and crystallization proceeded to produce rocks of the main zone, which has elevated and more uniform $^{87}Sr/^{86}Sr$ ratios.

Most of the data necessary for evaluating the feasibility of this model are unavailable, but considerations presented below suggest that *in situ* contamination is an unlikely explanation for the Sr-isotope variations. It seems unlikely that the contamination process was as short-lived as would be suggested by the thinness of the Merensky unit, and that it ceased abruptly, as indicated by the more uniform ratios in the Bastard unit. During the short contamination interval the magma must have been rapidly and efficiently mixed because rocks at this level in both the eastern and western lobes of the complex have similar Sr-isotope compositions (see Table 1 and ref. 1). If contamination occurred at the roof of the intrusion, transport of the contaminating Sr to the crystallization front at the base implies whole-magma convection. Although this possibility cannot be excluded, it seems more likely that contamination at the roof would cause self-stratification of the magma with convection cells confined to several layers[5], thus inhibiting thorough mixing of the magma. In the Rustenburg area the Merensky unit is orders of magnitude thinner than the main zone, and, using the principle of balancing the heat budget by assuming that the amount of melting in the wall rocks is roughly equivalent to the amount of crystallization, we conclude that a very small proportion of contaminant, much less than 1%, would be mixed in with the main zone. To produce the significant elevation of $^{87}Sr/^{86}Sr$ from 0.7064 to 0.7075 the contaminant must have very high Sr and/or $^{87}Sr/^{86}Sr$. Transvaal supergroup sediments that host the complex have low $^{87}Sr/^{86}Sr$ ratios[1,7]. Felsites of the Rooiberg group which form the roof of the intrusion have low Sr concentrations (average 70 p.p.m.; ref. 8) although no Sr-isotope data are available. Assuming that the precontaminated magma had Sr = 250 p.p.m. (calculated from Sr-concentration of cumulus plagioclase crystals in the Footwall unit) and that the extent of contamination was 1%, then the contaminant must have $^{87}Sr/^{86}Sr > 1.0$. This reduces to > 0.78 for 5% contamination. These ratios are high for felsites with $Rb/Sr \sim 2.5$ that were erupted shortly before emplacement of the Bushveld Complex and whose crustal or mantle precursors had very much lower Rb/Sr ratios.

The formation of main zone rocks from one or more new influxes of gabbroic magma is favoured by several workers[1,9–11].

Thermal and density contrasts between existing and new liquids and the nature of intrusion of the new magma would cause convective or turbulent mixing[12–15] of a presently unpredictable nature, as the exact properties of the magmas, the shape of the magma chamber, the rate of intrusion, and the position and shape of the conduits are unknown. Our detailed mineral and whole-rock composition data suggest that the new magma was compositionally similar to the existing magma, except that $^{87}Sr/^{86}Sr$ was >0.7075 and possibly >0.7086, as available data for the main zone (Table 1; ref. 1) vary between these limits.

The pattern of Sr-isotope variation (Fig. 1) precludes a behaviour suggested by some experiments[3,12] whereby the new magma flows to the bottom of the chamber displacing the existing magma upwards and after crystallizing a layer of crystals, mixes with it by convection. A more compelling model involves mixing of the magmas as the new influx enters the chamber. One possibility is that the deposition of the Merensky cyclic unit was concomitant with progressive influx and efficient mixing of the new magma into the existing liquid. The increasing $^{87}Sr/^{86}Sr$ ratios would therefore reflect the increasing proportion of new magma in the crystallizing mixture. The isotope data require that the influx ceased at the time the base of the Bastard unit was accumulating but the development of cyclic units and the similarity of mineral composition variations through the Merensky and Bastard units are difficult to reconcile with this restriction.

The possibility we prefer is one where the new magma entering the chamber mixes with the existing liquid and the Merensky and succeeding cyclic units form by accumulation of crystals precipitating from the blended magmas. This model would presumably result in a sharp step-like increase in $^{87}Sr/^{86}Sr$ at the base of the Merensky unit, contrary to what is observed. However, we suggest that whole-rock $^{87}Sr/^{86}Sr$ ratios in the Merensky unit were subsequently modified by infiltration of intercumulus liquid from the Footwall unit, a process described elsewhere[3,16]. This upward migrating liquid would displace or mix with that in the Merensky unit and the proportion of Sr with the isotopic signature of the footwall would decrease with height through the overlying crystal pile. The $^{87}Sr/^{86}Sr$ of the intercumulus material would therefore vary with the proportion of Sr introduced from the footwall, and the pattern depicted in Fig. 1 could result.

Although we have not been able to demonstrate directly the mixed isotopic character of Merensky cyclic unit rocks, comparison of data for M-7CPL with M-8WR (Table 1) is suggestive. Sample M-7CPL is of plagioclase primocrysts separated from enclosing orthopyroxene oikocrysts and these have $^{87}Sr/^{86}Sr = 0.70705$, approaching values typical of the main zone. The whole-rock sample M-8 comprises plagioclase primocrysts and intercumulus plagioclase and orthopyroxene and has $^{87}Sr/^{86}Sr = 0.70659$ which is close to values typical of the Footwall unit despite its higher stratigraphical position. Three intercumulus plagioclase separates for the basal pyroxenites and the pegmatoid of the Merensky unit have $^{87}Sr/^{86}Sr$ ratios that are almost identical, within error, to the Footwall unit initial ratio. We recall that Hamilton[1] found similar ratios in pyroxenites from the lower part of the Merensky unit; this is consistent with our data because in these rocks most of the Sr is contained in the intercumulus phases.

Our data support a role for a new magma influx, magma mixing and the process of infiltration metasomatism in the genesis of the Merensky pegmatoid. At this stage the implication for the origin of the associated PGE mineralization is unclear, as isotopic variations across the PGE-mineralized UG-2 layer have yet to be documented. If our interpretation of the Sr-isotope data for the Merensky unit is valid, models for PGE mineralization in layered igneous rocks should consider these processes.

The CSIR, Pretoria, and Johannesburg Consolidated Investment Co. provided financial support. Isotopes were determined at the Open University, UK and J.S.M. thanks Chris Hawkesworth and Professor Ian Gass for hospitality.

Age constraints on the proposed Plio–Pleistocene boundary stratotype at Vrica, Italy

John D. Obradovich*, Charles W. Naeser*, Glen A. Izett†, Giancarlo Pasini‡ & Giulio Bigazzi§

* US Geological Survey, Denver Federal Center, Denver, Colorado 80225, USA

‡ Istituto di Geologia Marina del Consiglio Nazionale delle Ricerche, Bologna, Italy
§ Istituto di Geocronologia e Geochimica Isotopica del Consiglio Nazionale delle Ricerche, Pisa, Italy

Estimates[1–4] of the age of the stratotype Plio–Pleistocene boundary in Italy range from 1.65 to 2.5 Myr. We aim here to clarify this dating confusion, and we present new radiometric data on ashes from the proposed stratotype section, Vrica, Italy which indicate that the Plio–Pleistocene boundary must be less than 2 Myr old. Biostratigraphical criteria—the first appearance datums (FADs) and last appearance datums (LADs) of planktonic foraminifera and calcareous nannoplankton tied to the magnetic reversal chronology—suggest that this boundary may be nearer to 1.7 Myr. Attempts to make the boundary far older than this are without basis.

Haq *et al.*[1] have applied the calcareous nannoplankton and planktonic biochronological framework established from palaeomagnetically-dated deep sea cores to the section at Le Castella, southern Italy and estimated an age of 1.6 Myr for the Plio–Pleistocene boundary. (This age is now revised to 1.65 Myr based on the use of the newly adopted decay constants for ^{40}K (ref. 5).) Note that although the section at Le Castella was proposed at the Seventh INQUA Congress as a section suitable for defining the Plio–Pleistocene boundary stratotype

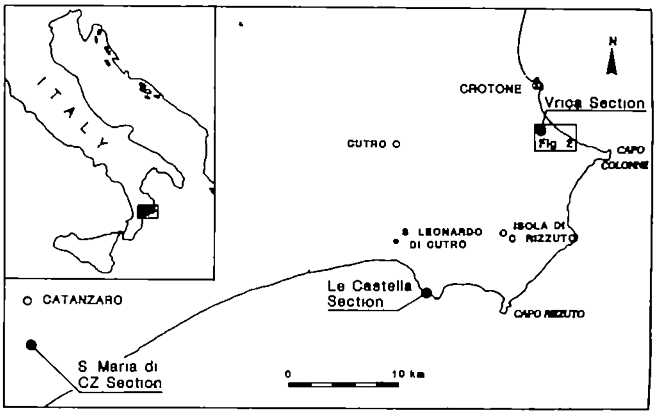

Fig. 1 Location of the Plio–Pleistocene sections at Vrica and Le Castella, and sampling localities (Calabria, Italy).

0028–0836/82/260055—05$01 00

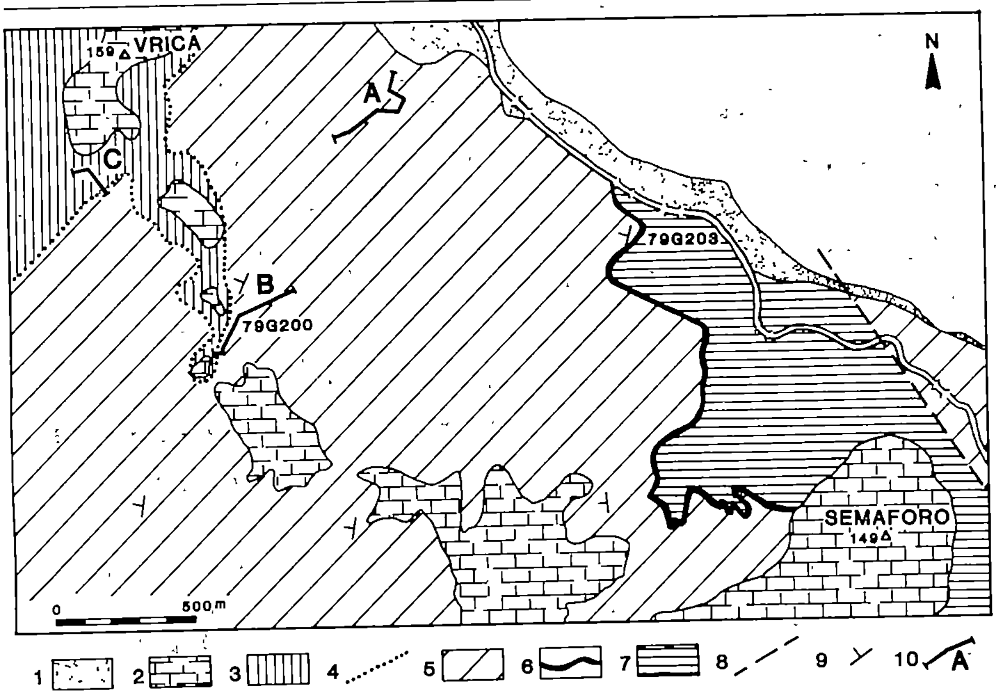

Fig. 2 Geological sketch map of the Vrica area, modified from Selli *et al.*[3]. 1, Beach sand and dunes; 2, calcarenites and sands of the marine terrace ('Milazzian'); 3, grey marly silty clays with sapropelic intercalations (early Pleistocene); 4, first appearance of *Hyalinea baltica*, 35 m above the *m* marker bed ash (<1.99 Myr); 5, grey marly silty clays with sapropelic intercalations (early Pleistocene, upper and middle Pliocene; the terminology for the Pliocene follows that of Italian workers); 6, lower volcanic ash horizon (2.22 Myr); 7, grey clays (middle Pliocene); 8, faults; 9, dip; 10, intervals sampled for the reconstruction of the columnar section going from the base of unit X to the top of unit Z (see Fig. 3, after ref. 16.).

this recommendation has never been officially accepted. Moreover, Colalongo *et al.*[6] have demonstrated the presence of a hiatus at the height of the 'marker bed' of Emiliani *et al.*[7] (considered by many to coincide practically with the Plio–Pleistocene boundary) at the Le Castella section[8,9]. Selli *et al.*[3] proposed that a new boundary stratotype at the Vrica section (Figs 1, 2) be accepted because of the continuity of section, better exposures, a thicker interval above and below the boundary, and an equally good fossil record. They reported several age determinations on a volcanic ash, termed the *m* marker bed, and a pumice block immediately above it in the short interval where the Plio–Pleistocene boundary would fall (Fig. 3): These ages, based on the K–Ar (Savelli in ref. 3) and fission-track, F-T (Bigazzi and Bonadonna in ref. 3) methods, ranged from 2.0 to 2.2 Myr. An even older age of 2.5 Myr has been determined by Boellstorff[4] using the F-T method on glass shards from the *m* marker bed. All of these ages, however, are far older than the age suggested by Haq *et al.*[1]. Given these divergent results we collected ash samples at Vrica and other localities where volcanic tephra are associated with sediments of late Pliocene or early Pleistocene age. At Vrica we collected the *m* marker bed ash and a Pliocene ash that is 280 m lower in the section.

Collecting the Pliocene ash was comparatively easy as the ash is thick (20 cm) and its lower part is relatively coarse. This ash is characterized by the presence of hornblende, plagioclase, and zircon. We obtained concordant ages of 2.22±0.03 Myr (K–Ar, hornblende); 2.0±0.16 Myr (F-T, zircon), and 2.2±0.2 Myr (F-T glass) (Tables 1*a* and 2). However, these results are: (1) in disagreement with the ages of 3.1 and 3.4 Myr previously determined by Dymond (in Selli[10]) using the K–AR method on glass shards from separate samples of the same Pliocene ash bed. One of these samples comes from the same locality where we collected our sample (79G203 in Fig. 2), the other comes from the environs of St Leonardo di Cutro (ref. 10 and R. Selli, personal communication); (2) younger than the 2.5 Myr age reported by Boellstorff[4] for the *m* marker bed ash which is 280 m higher in the section at Vrica; (3) the same as the 2.2±0.2 Myr age determined by Savelli[3] for glass shards from the *m* marker bed ash, though recalculation based on the data given in ref. 3 indicates an age of 2.27 Myr; and (4) almost the same age for the *m* marker bed ash of 2.07±0.33 Myr determined by Bigazzi and Bonadonna on glass shards (in ref. 3). Clearly something was wrong.

It was found that the sample of ash dated by Bigazzi and Bonadonna inadvertently had two labels attached to it, one indicating the sample to be the Pliocene ash and the other the *m* marker bed ash. Instrumental neutron activation analysis (INAA) of the glass dated by Bigazzi and Bonadonna and that of the Pliocene ash we collected in 1979 indicate that they are indeed the same ash. That is, the supposed *m* marker bed ash dated by Bigazzi and Bonadonna is actually the Pliocene ash and their result of 2.07±0.33 Myr agrees with our determinations.

Table 1 Analytical data for the K–Ar age determinations

DKA no.	Sample no.	Mineral	%K	Moles ^{40}Ar* g^{-1} (×10^{-11})	% Rad. Ar	Age (Myr)±1σ
a, **Pliocene ash**						
3864	79G203	Hornblende	0.805 (FL)	0.311	40.8	2.22±0.05
3936	79G203	Hornblende	0.781 (ID)	0.301	32.9	2.22±0.04
b, *m* **Marker bed ash**						
3861	79G201 (−80m)	Biotite (S)	7.21 (FL)	3.250	33.5	2.60±0.05
3935	79G201 (+80m)	Biotite (S)	7.21 (FL)	2.882	32.1	2.30±0.05
3965	79G200 (−80m)	Biotite (P)	7.03 (FL)	2.601	23.3	2.13±0.05
4128	79G200 (+80m)	Biotite (P)	6.99 (ID)	2.410	12.5	1.99±0.08
c, **Vrica pumice**						
4201		Hornblende	0.377 (ID)	0.154	7.6	2.35±0.16

Decay constants for ^{40}K (ref. 5): $^{40}K/K = 1.167\times10^{-2}$ atom %; $\lambda_\beta = 4.962\times10^{-10}\ yr^{-1}$; $\lambda e + e' = 0.581\times10^{-10}\ yr^{-1}$. ID, isotope dilution; FL, flame photometry.

Table 2 Analytical data for the F-T age determination

Sample no.	Mineral	Correction method[17]	D^S/D^I or Temperature	$\rho_s \times 10^5$ tracks cm^{-2}	$\rho_i \times 10^{15}$ tracks cm^{-2}	$\Phi \times 10^{15}$ n cm^{-2}	App. age (Myr)	Corr. age (Myr)	$\pm 1\sigma$ (Myr)	Grains	$r, \bar{s}$
79G203	Zircon	—	—	3.21 (95)	94.8 (1404)	1.01	2.0	—	0.16	12	0.98 (r)
79G203	Glass	size	0.83	0.0281 (316)	0.235 (1046)	0.190	1.37	1.9	0.2	200/130	3.8% ($\bar{s}$)
79G203	Glass	plateau	200 °C	0.0272 (307)	0.144 (560)	0.190	—	2.2	0.2	230/100	4.8% ($\bar{s}$)

D^S/D^I, size ratio of spontaneous to induced tracks, shown for the size corrected age only. Temperature, heating temperature for the plateau age. ρ_s, ρ_i, Spontaneous and induced track densities respectively. (), Number of tracks counted. Φ, Neutron fluence, referred to the standard SRM 962 of the NBS. App. age, apparent age before any correction. Corr. age, corrected age. Grains, the number of glass grains used for counting the spontaneous and induced tracks respectively are shown; for zircon the total number of grains counted using the external detector method. $\bar{s}$, Experimental standard deviation, in per cent, of the induced track counting; r, correlation coefficient. Decay constant for the spontaneous fission of ^{238}U $= 7.03 \times 10^{-17}$ yr^{-1}: although the Denver and Pisa F-T groups routinely use slightly different values for the decay constant the same value is used here for consistency. The glass irradiations were performed in the Pavia University (Italy) reactor and the zircons were irradiated at the USGS reactor, Denver, Colorado.

J. Dymond (personal communication) revealed that unpublished ^{40}Ar/^{39}Ar stepwise heating data for the sample of Pliocene ash at St Leonardo di Cutro indicates that the glass shards contain excess radiogenic argon. We believe that this is also true of the other ash sample from Capo Colonne.

With respect to Savelli's determination of 2.27 Myr (revised) for the *m* marker bed ash we can only stress that K–Ar ages based on total fusion of glass shards are to be viewed with caution[11]. Without independent criteria such as Dymond's ^{40}Ar/^{39}Ar stepwise heating approach or dating of a more reliable uncontaminated mineral phase of the ash, there is no way to appraise the results.

We think that Boellstorff probably dated the Pliocene ash but we have not been able to verify this point. However, his age of 2.5 Myr, whether for the Pliocene ash or the *m* marker bed ash, is inconsistently old compared with our radiometric data and current biostratigraphic data. The calcareous nannoplankton *Gephyrocapsa aperta* appears 17 m below the Pliocene ash at Vrica[13]. In deep sea cores *G. aperta* makes its first appearance at 2.36 Myr (ref. 2) but in the Mediterranean its appearance could be younger. With these constraints Boellstorff's result is too old for the Pliocene ash and particularly the *m* marker bed ash.

Collection of the *m* marker bed ash proved difficult because it is at most 2–3 thick and is quite lenticular. Two samples of the ash were collected. A primary sample of about 1 kg was collected very carefully to avoid any extraneous material. The exterior surface of each solid fragment of ash was removed with a knife to avoid possible contamination. A much larger secondary sample was collected with less caution. This ash is characterized by the presence of biotite and plagioclase. Unfortunately the absence of zircon prevented dating by the F-T method as the glass shards from this particular ash are not suited to dating by this method.

Our efforts to date the *m* marker bed ash have been only partially successful. Biotite from the secondary sample yielded an age of 2.6 Myr, older than that of the underlying Pliocene ash (see Table 1*b*). We concluded that the biotite sample is contaminated and separated the secondary and primary samples into two size fractions, +80 mesh and −80+100 mesh. Contamination is probably greater in the finer fraction and that fraction should yield the older age. The results in Table 1*b* indicate that this is so. The coarser fraction of the primary sample yielded the youngest age: 1.99 Myr.

Electron microprobe analysis for potassium, iron, magnesium, titanium, and calcium were performed on each of the four biotite separates to determine, if possible, the level of contamination. Two distinct classes of detrital biotite are evident. These are characterized by (1) higher Fe, slightly higher K, and lower Mg, (2) lower Fe, slightly lower K, and higher Mg contents than the normal population of primary biotite. Several grains which showed lowered levels for all of the elements examined were excluded from the tabulation as it was

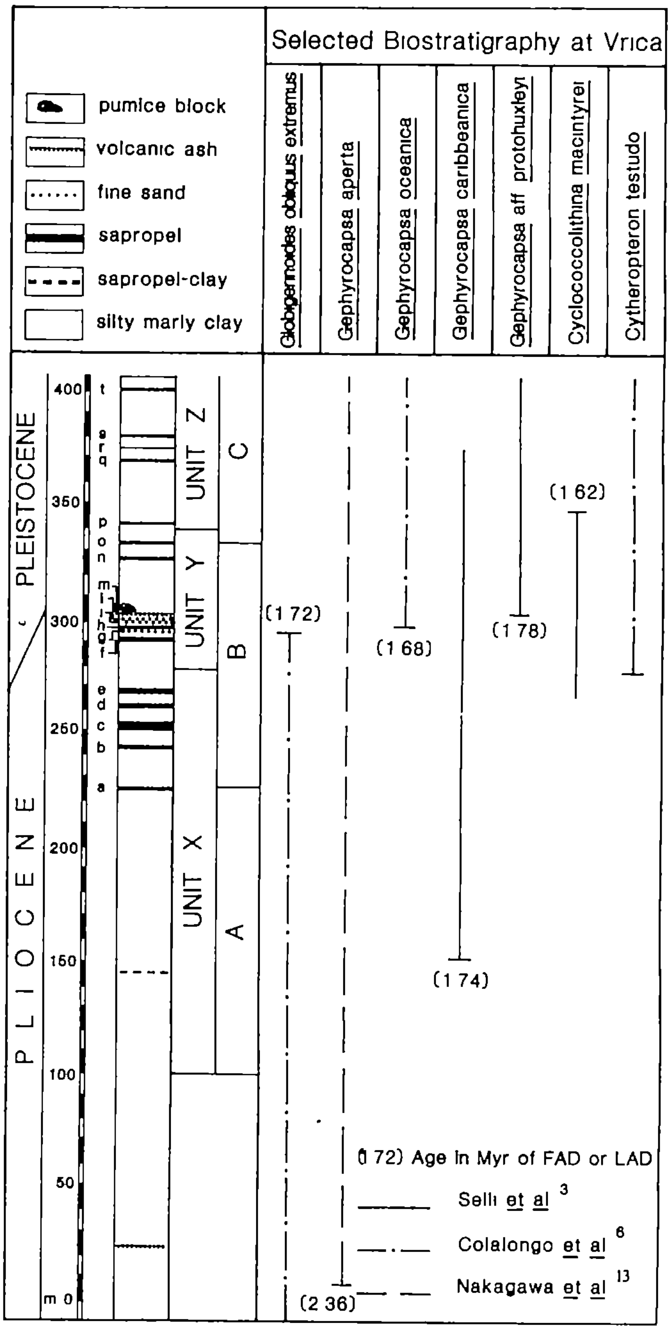

Fig. 3 Selected biostratigraphical data at Vrica. The columnar section is taken from ref. 3 (from the boundary of unit X upwards) and ref. 13 (below the lower boundary of unit X, simplified).

thought that they probably represented leached biotite grains. The detrital grains can be listed as follows:

Primary	(+80 mesh)	2 grains out of 102
	(−80+100 mesh)	6 grains out of 127
Secondary	(+80 mesh)	1 grain out of 110
	(−80+100 mesh)	6 grains out of 132

The limited number of grains examined may not give a realistic appraisal of the true level of contamination but these samples are definitely contaminated.

In retrospect, then, the age of the *m* marker bed and the proposed Plio–Pleistocene boundary-stratotype which should be placed close to this level should be younger than 1.99 ± 0.08 Myr.

Savelli and Mezzetti[12], Selli *et al.*[3], and Colalongo *et al.*[6] have repeatedly stressed the importance of the presence of a block of 'perfectly preserved pumice' immediately above the *m* marker bed ash at Vrica. This statement needs to be clarified.

First, one might infer from these reports that the pumice was actually collected at Vrica. However, the pumice block was collected from a quarry west of the city of Crotone some 4 km north of the Vrica section. One of us (G.P.), however, is convinced that the level at which the pumice block was found can be correlated to a level located ~1 m above the *m* marker bed at the Vrica section. Second, there is a large dissimilarity in the mineralogy and chemistry of the pumice and the *m* marker bed ash. The pumice contains phenocrysts of hornblende and plagioclase while the ash contains biotite and plagioclase. INAA of the glass fraction indicates that the pumice block is very similar to but not an exact equivalent of the Pliocene ash.

Approximately 250 g of the pumice was sent to Denver and sufficient hornblende for a single analysis was recovered. The K–Ar age of 2.35 ± 0.16 Myr (Table 1*c*) obtained was interpreted as indicating that the pumice block has been reworked from an older pumice layer and thus has no relevance to the age of the *m* marker bed.

The question really is just how much younger than 1.99 ± 0.08 Myr might the actual age of the *m* marker bed be? Selli *et al.*[3] used the sparsely available radiometric data and drilling efforts near Semaforo (Fig. 2) to propose rates of sedimentation of 35–48 cm kyr^{-1} for the 1,250 m between the top of the Messinian which they assumed to be 6 or 7 Myr old and the Pliocene ash previously dated at 3.4 Myr. If we use the more commonly accepted age of 5 Myr for the Miocene–Pliocene boundary and the 2.2 Myr age for the Pliocene ash we get an average rate of 45 cm kyr^{-1}. This rate is still in agreement with Selli *et al.*[3] because of the change in age of ~1 Myr at each end of the stratigraphical section. Assuming continuous sedimentation and applying this rate to the 280 m between the Pliocene ash and the *m* marker bed gives an age of ~1.6 Myr for the *m* marker bed. However, average rates of sedimentation must be used with caution.

Ultimately the resolution of the problem of the age of the *m* marker bed and, of course, the age of the Plio–Pleistocene boundary may rest on biostratigraphical and palaeomagnetic criteria. Nakagawa *et al.*[13] have presented a preliminary version of the magnetostratigraphy of the Vrica section, but later circulated results and interpretations quite different and conflicting: therefore the treatment of this topic is at present impractical. Thus we give here only a brief treatment of the relevant biostratigraphy at Vrica.

Berggren *et al.*[2] have summarized the numerous first appearance datums (FADs) and last appearance datums (LADs) of certain planktonic foraminifera and calcareous nannoplankton which have been recognized in deep sea cores and related to the magnetic reversal time scale. In using FADs and LADs one must keep in mind that the first appearance datum at any specific geographical locality may not coincide in time and may be younger than the first evolutionary appearance datum just as the last appearance datum may simply represent the disappearance of a particular species from a certain locality or region and so may be older than the true world-wide extinction of that species. Among the FADs and LADs mentioned by Berggren *et al.*[2] and by Haq *et al.*[1] the following have been recognized at Vrica (see Fig. 3 for the distribution within the section).

Planktonic foraminifera: (1) LAD of *Globigerinoides obliquus* occurs in deep sea cores at the top of the Olduvai normal polarity event with an interpolated age of 1.72 Myr (ref. 2). At Vrica *G. obliquus* is recognized at the subspecific level as *G. obliquus extremus* but this is in the same concept of *G. obliquus* recognized by Haq *et al.*[1], mentioned by Berggren *et al.*[2] and confirmed by Berggren (personal communication).

Calcareous nannoplankton: (1) LAD of *Cyclococcolithina macintyrei* occurs in deep sea cores above the Olduvai normal polarity event and has an interpolated age of 1.62 Myr (ref. 2, p. 285). (2) FAD of *Gephyrocapsa oceanica* in deep sea cores occurs just above the top of the Olduvai normal polarity event and has an interpolated age of 1.68 Myr (ref. 2, p. 284). (3) FAD of *Gephyrocapsa caribbeanica* in deep sea cores occurs just below the top of the Olduvai normal polarity event and has an interpolated age of 1.74 Myr (ref. 2, p. 285). The utility of the FAD of this species may be reduced because of conflicting concepts of it held by various investigators (ref. 14, p. 19). If the FAD of *G. caribbeanica* at Vrica section really occurs 73 m below sapropel layer a as indicated by Selli *et al.*[3] (Fig. 3), then we are faced with a troublesome fact. The FADs of *G. oceanica* and *G. caribbeanica* are separated by some 140 m of sediment. according to Berggren *et al.*[2] this interval would represent ~60,000 yr giving an average rate of sedimentation of ~230 cm kyr^{-1}, an inordinately high rate for this part of the section. (4) FAD of *Gephyrocapsa protohuxleyi* in deep sea cores is within the top of the Olduvai normal polarity event but occurs slightly before the FAD of *G. caribbeanica* (ref. 1, Fig. 5). If we adopt for the Olduvai the age limits proposed by Berggren *et al.*[2] (1.72–1.88 Myr), the FAD of *G. protohuxleyi* has an interpolated age of 1.78 Myr. At Vrica *G.* aff *protohuxleyi* has been recognized and occurs ~10 m above the FAD of *G. oceanica*. (5) FAD of *Gephyrocapsa aperta* occurs in deep sea cores below the Olduvai normal polarity event and has an interpolated age of 2.36 Myr (ref. 2, p. 284). At Vrica *G. aperta* makes its first appearance 17 m below the Pliocene ash whose age is 2.22 Myr.

Figure 3 shows the age assignments for the various FADs and LADs in parentheses. Despite the qualifications cited above an age of ~1.7 Myr for the *m* marker bed would be consistent with the biostratigraphical data.

According to the recent resolution of the joint meeting of the INQUA Subcommission 1 − *a* (= ICS Working Group N/Q Boundary) and the IGCP Project 41 made during the International Geological Congress in Paris (July 1980), "the N/Q boundary should be placed in the Vrica section taking into account the FAD of the early cold guest *Cytheropteron testudo* (whatever its palaeoclimatic significance could be), which occurs in Vrica 10 m above Sapropel *e*. [Colalongo *et al.*[6,9], and Colalongo and Sartoni[15], have demonstrated that in the Vrica section the FAD of *C. testudo* is accompanied by palaeontological events (FADs and LADs of planktonic foraminifera and calcareous nannofossils) that are useful for long-distance correlations.] On the other hand, there are alternative possibilities for selecting a level as the N/Q boundary stratotype in the Vrica section, within the stratigraphical interval between level *e* and the volcanic ash level *m*, which are closely related with the FAD of *C. testudo*, within a reasonably short time range."

Taking this resolution into account, it is apparent that the proposed Plio–Pleistocene Boundary stratotype in the Vrica section will fall close to 1.7 Myr and that all other published estimates suggesting an age of 2 Myr or more are inappropriate.

We thank W. Berggren, D. Hopkins, K. MacDougall, K. Pierce, and G. M. Richmond for their critical comments, Professor Jack Dymond for allowing us to cite his unpublished ^{40}Ar/^{39}Ar results, also G. Cebula, J. Groen, H. Mehnert, and K. Futa for technical assistance. J.D.O., C.W.N and G.A.I. are indebted to the National Geographic Society for financial assistance.

Brown adipose tissue thermogenesis is 'suppressed' during lactation in mice

Paul Trayhurn, Jenny B. Douglas & Martina M. McGuckin

Dunn Nutritional Laboratory, University of Cambridge and
Medical Research Council, Milton Road, Cambridge CB4 1XJ, UK

Brown adipose tissue is considered to be the main site of thermoregulatory non-shivering thermogenesis in the newborn of many mammalian species, in arousing hibernators, and in adult cold-adapted rats and mice[1–4]. Several recent studies have now suggested that the tissue may also be important in the regulation of energy balance. Evidence has been obtained indicating that the ability of genetically obese (*ob/ob* and *db/db*) mice to become obese on a normal energy intake is mainly due to reduced brown adipose tissue thermogenesis[5–7], and a reduction in the activity of the tissue has also been observed in rats made obese by lesions of the ventromedial hypothalamus[8]. In contrast, increases in thermogenesis in brown adipose tissue have been implicated in the immediate thermic effect of food[9] and in cancer cachexia[10], and a substantial augmentation of the activity of the tissue has been demonstrated in rats and mice exhibiting regulatory diet-induced thermogenesis as a response to chronic voluntary over-feeding[11–14]. Whether or not brown adipose tissue thermogenesis changes in other, more physiological, states where energy flux and metabolic efficiency are altered (independently of environmental temperature) has not been established. We now report that the thermogenic activity of brown adipose tissue is suppressed in mice during the 'physiological hyperphagia' of lactation, and show that this probably results in a substantial reduction in the energy requirement for maintenance of the lactating animal.

The animals used in this study were mice of the 'Aston' variety[15], aged between 2½ and 4 months. Pregnant and lactating animals were taken during their first or second litter, and each litter contained between 6 and 10 pups. Virgin females, housed in pairs, were used as controls. The temperature of the animal house was maintained at 21 ± 2 °C, and the mice were subject to a 12 h light/12 h dark cycle (light period from 07.00 h). All mice were given free access to both water and a low-fat commercial breeding diet (Spillers–Spratts Rodent Breeding Diet 1).

In the first experiments the weight, total protein content and cytochrome oxidase activity (E.C.1.9.3.1) of brown adipose tissue from the readily accessible interscapular site were determined for virgin mice and for mice at mid-lactation (days 9–12 post partum). A comparison was also made with mice during late pregnancy (see Table 1). The total amount of interscapular brown adipose tissue was greater in both the lactating and pregnant animals than in the virgin mice. This increase is probably due to increased lipid deposition, as the total protein content of the tissue was lower in both the pregnant and lactating animals. The cytochrome oxidase activity in brown adipose tissue of the lactating mice was reduced to half the level in the virgin animals, indicating that during lactation there is a substantial decrease in the overall oxidative capacity of the tissue. The cytochrome oxidase activity was also reduced in late pregnancy, to a value between that of the virgin and lactating animals.

Table 1 Weight, protein content and cytochrome oxidase activity of interscapular brown adipose tissue from virgin and lactating mice

	Virgin	Pregnant	Lactating
Tissue weight	68.5 ± 3.8	102.6 ± 8.8‡	93.7 ± 3.5‡
(mg)	(17)	(6)	(12)
Total protein	11.7 ± 0.5	9.6 ± 0.4*	8.2 ± 0.4‡
content (mg)	(17)	(6)	(12)
Total cytochrome			
oxidase activity	17.5 ± 0.8	13.2 ± 0.6†	8.8 ± 1.1‡
(μmol cytochrome	(15)	(6)	(10)
c oxidized per min)			

Mice were killed by cervical dislocation and the interscapular brown adipose tissue rapidly removed, and trimmed free of other tissues. The cytochrome oxidase activity of brown adipose tissue was measured spectrophotometrically[28], and the total protein content assayed by a modified Lowry method[29] using BSA as a standard. The results are given as mean ±s.e.m., with the numbers of animals shown in parentheses.

* $P < 0.05$; † $P < 0.01$; ‡ $P < 0.001$, compared with the virgin animals (Student's *t*-test).

The principal mechanism for thermogenesis in brown adipose tissue is via a proton conductance pathway across the inner mitochondrial membrane, which results in the uncoupling of respiration from ATP synthesis[16]. The proton conductance pathway can be blocked by purine nucleotides, such as GDP, which bind to a specific 'uncoupling' protein of molecular weight 32,000 (refs 17, 18). The activity of the proton conductance pathway is generally assessed from the extent to which radioactively labelled purine nucleotides bind to brown adipose tissue mitochondria[19–22]. Table 2 shows the results of a GDP-binding study of virgin, pregnant and lactating mice. Compared with the virgin mice, GDP binding was much lower in both early (days 1–3 post partum) and mid-lactation; it was also low during late pregnancy. Binding was lowest at mid-lactation and was not significantly increased 24 h after the pups had been abruptly weaned. These results suggest that the activity of the thermogenic proton conductance pathway is substantially reduced during pregnancy and lactation in mice.

The full extent of the reduction in brown adipose tissue thermogenesis in lactating mice was assessed by reference to the level of GDP binding in virgin animals acclimated for 3 weeks at an environmental temperature (33 °C) where there is

Table 2 GDP binding to brown adipose tissue mitochondria from virgin and lactating mice

	GDP bound (pmol per mg mitochondrial protein)
Virgin	249.4 ± 24.7 (10)
Pregnant	88.0 ± 7.4 (7)*
Lactating (early)	93.3 ± 14.6 (6)*
Lactating (mid)	56.2 ± 5.5 (8)*
Abruptly weaned at mid-lactation	65.5 ± 5.0 (6)*
Virgin, adapted at 33 °C	55.1 ± 5.0 (9)*

Mice were killed by cervical dislocation and brown adipose tissue rapidly removed from the interscapular, subscapular and dorso-cervical sites. Mitochondria were then prepared as described by Cannon and Lindberg[30]. GDP binding was measured by incubating the mitochondria with 10 μM ^{3}H-GDP at 20 °C, *p*H 7.1, for 7 min, as described previously[7,14]. (^{3}H-GDP and ^{14}C-sucrose were obtained from Amersham.) The results are given as mean ±s.e.m., with the number of observations shown in parentheses. For each assay, mitochondria were obtained from 1–2 mice.

* $P < 0.001$, compared with the virgin animals (Student's *t*-test).

Table 3 Respiration rates in brown adipose tissue mitochondria from virgin and lactating mice

Additions	Mitochondrial respiration (nmol O_2 per min per mg mitochondrial protein)	
	Virgin	Lactating (mid)
–	110.7 ± 18.9	53.3 ± 9.0*
BSA (2.5 mg ml^{-1})	308.2 ± 15.3	188.2 ± 13.4†
GDP (1 mM)	131.1 ± 10.8	149.4 ± 10.3(NS)
Change in rate with GDP	-177.2 ± 18.6	-38.8 ± 8.7†

Brown adipose tissue mitochondria were prepared as described in Table 2 legend. Respiration was measured at 25 °C in a Yellow Springs YSI model 53 oxygen electrode, using medium (pH 7.1) containing 100 mM sucrose, 10 mM glycylglycine and 5 μM rotenone, with 10 mM α-glycerophosphate as substrate[24]. The results are mean ±s.e.m. for 6 groups of virgin and 6 groups of lactating mice (each group consisted of mitochondria obtained from 2 mice).

* $P < 0.05$; † $P < 0.001$, compared with the virgin animals (Student's t-test). NS, not significant ($P > 0.05$).

no requirement for non-shivering thermogenesis[23]. The results obtained with mice in these conditions (Table 2) were almost identical to those observed at mid-lactation. A Scatchard analysis of binding data showed that the reduced GDP binding in lactating mice was due to a reduction in the number of binding sites, and not to any change in affinity; the apparent dissociation constant (K_D) was approximately 3 μM at pH 7.1 for both virgin and lactating animals.

The GDP-binding assay is a physicochemical index of the proton conductance pathway. To obtain a more direct physiological measure of the thermogenic activity of brown adipose tissue mitochondria during lactation, mitochondrial respiration was determined (with α-glycerophosphate as substrate) in the presence and absence of exogenous GDP. The results in Table 3 show that in the presence of bovine serum albumin (BSA), which removes the inhibitory effects of endogenous fatty acids on the activity of α-glycerophosphate dehydrogenase[24,25], the mitochondrial respiration rate was significantly higher in virgin than in lactating mice. Following the addition of GDP, to recouple the mitochondria and restore respiratory control, the respiration rate fell much more in the virgin than in the lactating mice, and there was no longer any significant difference between the two groups. The difference between the respiration rates before and after adding GDP was almost 5 times higher for the virgin than for the lactating mice; thus, brown adipose tissue mitochondria from lactating mice seem to be much more fully 'coupled' than those from virgin animals.

The results presented here clearly demonstrate that thermogenesis in brown adipose tissue is suppressed in lactating mice, and the suppression is such that the thermogenic activity is similar to that of mice adapted to thermoneutral conditions. Alterations in the metabolism of brown adipose tissue in lactation have been observed previously by Agius and Williamson[26,27] in studies on lipogenesis. Not only is thermogenesis for thermoregulatory purposes inhibited in brown adipose tissue during lactation, but the increased food intake of the lactating animal does not result in a dietary-induced stimulation of the tissue—in contrast to the response invoked during overfeeding in normal, non-lactating, rats and mice[11-14]. This is, of course, a rational response as substrates which would otherwise be dissipated in brown adipose tissue as heat are available for the synthesis of milk[26,27].

The inhibition of brown adipose tissue thermogenesis would be expected to have a significant energy sparing effect on the lactating animal. To obtain an estimate of the possible (maximum) quantitative importance of such an effect, we have measured the energy intake of virgin mice, aged 3 months, adapted at 21 °C and at 33 °C (thermoneutrality); the difference should reflect the normal energy flux through brown adipose tissue and those tissues (for example, heart) which have a supportive role in thermogenesis[3,4,6,13]. At 21 °C the gross energy intake of the virgin mice was 76 kJ per day, while at 33 °C it was 45 kJ per day, giving a figure of 31 kJ per day for the energy expenditure on thermogenesis at 21 °C. Thus, if *in vitro* experiments on mitochondrial respiration and GDP binding accurately reflect the activity of brown adipose tissue *in vivo*, the suppression of brown adipose tissue thermogenesis in the lactating mouse could conserve as much as 31 kJ per day, and this is equivalent to 40% of the maintenance energy requirement of the normal, non-lactating, animal.

The most likely explanation for the results obtained here is either that during pregnancy and lactation there is a distinct physiological adaptation for energy conservation (mediated by prolactin?), or that the increased metabolic heat production which results from fetal growth and milk synthesis is sufficient to obviate the need for any specific thermoregulatory heat production. Whichever explanation is correct, the inhibition of brown adipose tissue thermogenesis would be expected to have a significant effect on the overall energy expenditure and energy requirement of the lactating mouse. Whether there are implications from the observations presented here for other (larger) species, including man, is not clear. In conclusion, our results, together with a previous study on lipogenesis following intragastric feeding[26], indicate that the lactating animal may be a valuable model in which to investigate the regulation of thermogenesis in brown adipose tissue.

We thank Drs W. A. Coward and D. Isler for valuable discussions, and Mr A. Kimmerling for technical assistance.

Relationship of β-adrenoreceptor density to fitness in athletes

J. Butler, M. O'Brien, K. O'Malley & J. G. Kelly

Departments of Clinical Pharmacology and Anatomy, Royal College of Surgeons in Ireland, St Stephens Green, Dublin 2, Eire

Physical training in man results in a decreased heart rate at rest[1,2], associated with an apparent decrease in the activity of the sympathetic nervous system[1,3]. One possible mechanism for this would be alterations in β-adrenoreceptor density with training. Exercise produces large increases in plasma catecholamine concentrations[4,5]. Moreover, lymphocyte β-adrenoreceptor density in man is inversely correlated with plasma and urinary noradrenaline concentrations and is positively correlated with cardiac sensitivity to isoprenaline[6]. Thus,

0028-0836/82/260060—03$01.00

alterations in β-adrenoreceptor density in the cardiovascular system might be reflected in changes in lymphocyte β-adrenoreceptor density. We have now measured lymphocyte β-adrenoreceptor density in a group of athletes of varying degrees of fitness before and after they embarked on an intensive training programme. Our results show clear correlations between degree of physical fitness and receptor density and we conclude that decreases in sympathetic nervous system responsiveness following physical training are related to decreases in β-adrenoreceptor density.

Observations were made on 16 male swimmers aged 14–24 yr. The subjects were of varying fitness and were about to embark on a 2-month intensive training programme. A venous blood sample (30 ml) was obtained from each subject at 10.30 a.m. Lymphocytes were isolated using the method of Boyum[7] and β-adrenoreceptor density was measured by a radioligand binding method similar to that of Williams *et al.*[8]. At 11 a.m. on the same morning, each subject underwent submaximal exercise on a Monarch bicycle ergometer and fitness levels were then assessed using predicted aerobic capacity (maximal oxygen intake, max VO_2) from the Astrand–Rhyming nomogram[9]. Results for max VO_2 and adrenoreceptor densities were only correlated at the completion of the study. No subject was receiving any drugs.

Pre-training max VO_2 was 24–61 ml per kg per min (mean, 49.6±2.3 s.e.m.) and pre-training β-adrenoreceptor density varied over 1,538–385 receptors per lymphocyte (mean, 1,062±97 s.e.m.) (Fig. 1*a*). There was a complex inverse relationship between max VO_2 and β-adrenoreceptor density (Spearman's $\rho = 0.75$, $P < 0.001$). At low to average levels of fitness, β-adrenoreceptor density was in the region of 1,000–1,500 sites per cell, in good agreement with values previously reported by us in young people of average physical fitness[10]. At higher levels of fitness, however, represented by max VO_2 values greater than 45–50 ml per kg per min, receptor density decreased sharply.

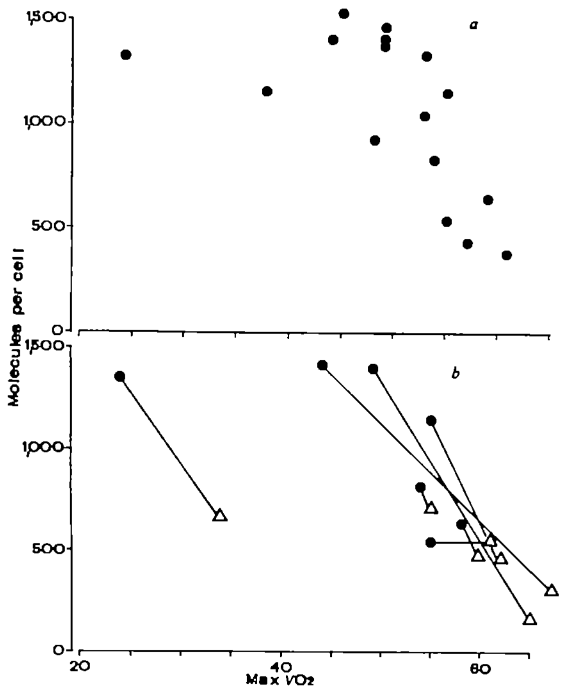

Fig. 1 *a*, Relationship between maximal oxygen intake (max VO_2 in ml per kg per min) and lymphocyte receptor density (as molecules of dihydroalprenolol specifically bound per cell), in 16 swimmers of varying fitness before embarking on a training programme. Lymphocyte β-receptor density was estimated by a method similar to that of Williams *et al.*[8]. Lymphocyte membranes (0.1 ml) equivalent to 2×10^6 cells were incubated with ^{3}H-dihydroalprenolol (102 Ci mmol^{-1} Amersham) at concentrations of 0.5–5.5 nM. The final volume was 0.2 ml. After incubation for 15 min at 37 °C the reaction was terminated by the addition of 2 ml ice-cold buffer (50 mM Tris, 2 mM $MgCl_2$, *p*H 7.6). Membranes were separated by immediate filtration through Whatman GFC filters which were then washed with three 2-ml volumes of buffer. Nonspecific binding was estimated in the presence of 10^{-5} M alprenolol. Numbers of specific dihydroalprenolol binding sites were calculated using Scatchard plots. *b*, Maximal oxygen uptake (ml per kg per min) plotted against lymphocyte receptor density (as molecules of dihydroalprenolol specifically bound per cell) in seven swimmers before (●) and after (△) a 2-month training programme.

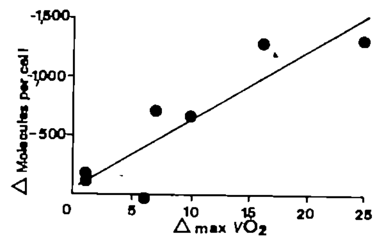

Fig. 2 Relationship between change in receptor density (as decrease in the number of molecules of dihydroalprenolol specifically bound per cell) and change in maximum oxygen intake (as increase in max VO_2, ml per kg per min) in the seven swimmers who underwent a 2-month training programme. The line of best fit, determined by linear regression analysis, is shown (correlation coefficient = −0.89, $P < 0.01$).

Seven subjects completed their training schedule satisfactorily and were reassessed. Figure 1*b* plots pre- and post-training values for max VO_2 and receptor density for each of these subjects. Training increased max VO_2 in every case, the mean pre-training value being 48.7±4.5 ml per kg compared with a mean post-training value of 58.1±4.1 ml per kg ($P < 0.05$, Student's *t*-test for paired data). After training, lymphocyte β-adrenoreceptor density in these seven subjects decreased from a mean of 1,074±152 receptors per cell to a mean of 458±78 ($P < 0.05$) and in all but one subject, receptor density decreased. The single exception showed an insignificant change in receptor density from 547 to 554 sites per cell. Those subjects showing the greatest increase in fitness also tended to show the greatest fall in lymphocyte β-adrenoreceptor density and there was a significant linear correlation between change in receptor density and change in max VO_2 (Fig. 2).

Our results show a clear, inverse relationship between physical fitness and lymphocyte β-adrenoreceptor density. Physical training can further reduce β-adrenoreceptor density and this reduction is proportional to changes in fitness. The most likely explanation involves changes in concentrations of circulating catecholamines, although effects of other exercise-related metabolic processes such as metabolic acidosis cannot be excluded. Exercise results in large increases in plasma catecholamine concentrations. These increases are slightly lower in trained subjects but are still substantial[5]. High concentrations of sympathomimetic amines in man, whether from exogenous or endogenous sources, result in a decreased responsiveness of lymphocytes to stimulation by these agents[11], associated with decreases in receptor density[12,13]. The reductions in receptor density at higher levels of physical fitness seen in the present study probably result from regular exposure to high concentrations of catecholamines. Fraser and colleagues[6] recently found evidence that these reductions could result in decreased sympathetic nervous system responsiveness and showed that low lymphocyte β-adrenoreceptor densities were associated with low cardiac sensitivity to isoprenaline.

We suggest that the decreased sympathetic nervous system responsiveness seen in athletes is due to a decreased β-adrenoreceptor density resulting from chronic exposure to high concentrations of catecholamines. Teleologically, this could represent a protective mechanism against chronic sympathetic nervous system stimulation. Physical fitness should be taken into account in studies involving measuring β-adrenoreceptor density or responsiveness.

Visual pigments in the four-eyed fish, *Anableps anableps*

J. A. Avery & J. K. Bowmaker

Department of Zoology and Comparative Physiology,
Queen Mary College, University of London, Mile End Road,
London E1 4NS, UK

The retinae of terrestrial and marine vertebrates generally contain the visual pigment, rhodopsin, whereas those of freshwater vertebrates contain porphyropsin[1,2]. The latter pigment absorbs light at longer wavelengths than rhodopsin and therefore has increased red sensitivity, which is possibly beneficial to animals living in water containing suspended particles since these may cause image degradation due to light scattering at short wavelengths. Many fish and amphibians have both types of pigment, and in some fish, the proportion of rhodopsin to porphyropsin is greater in the dorsal half of the retina[3]. In the bullfrog, *Rana catesbeiana*, the ventral retina contains only rhodopsin, whereas the dorsal retina has appreciable amounts of porphyropsin[4]. This may be attributable to the fact that the bullfrog often has only its eyes and nose protruding above the water surface, thus the dorsal part of the retina is used for aquatic vision and the ventral part for aerial vision. The 'four-eyed' fish, *Anableps*, is able to see simultaneously in air and water; it normally swims so that the eye is bisected by the water meniscus. Each eye has a single retina, but the dorsal part receives images from the water, and the ventral region receives aerial images[5,6]. Thus it has been suggested that the dorsal region should show more red dominance[7], with porphyropsins being restricted to this area. We have measured the absorbance spectra of the photoreceptors, and report here that the same visual pigments are present in the dorsal and ventral regions of *Anableps* retina.

A visual pigment molecule consists of a protein moiety, opsin, and a chromophore, based on either vitamin A_1 or A_2. Rhodopsins, generally found in the retinae of terrestrial and marine vertebrates, are based on vitamin A_1, whereas porphyropsins, found in freshwater vertebrates, are based on vitamin A_2. Using the same opsin, a vitamin A_2 pigment absorbs light at longer wavelengths than a vitamin A_1 pigment, hence porphyropsin has increased red sensitivity compared with rhodopsin.

Live specimens of *Anableps anableps* (obtained from a tropical fish supplier in London) were maintained in brackish water (specific gravity 1.005, pH 7–8, temperature 22–24 °C). The fish were dark-adapted overnight before an experiment. All procedures were then carried out under dim red light (Kodak safelight no. 2).

The fish were decapitated, and the eyes removed and stored in the dark at 4 °C until required. Each eye was cut into dorsal and ventral sections with a razor blade, using as a guide the horizontal corneal pigment band which marks externally the division between the two halves of the eye. The retina was removed from each section and placed in freshwater teleost Ringer's solution. A small piece of retina (~1 mm²) was cut from one of the retinal halves and prepared using a method similar to that described elsewhere[8]. Briefly, the tissue was cut into fragments with razor blades and squashed between two coverslips, which were sealed with paraffin wax to avoid evaporation. Microspectrophotometric measurements were made using a modified Leibman microspectrophotometer[9,10] under computer control, as described elsewhere[11]. The microspectrophotometer was programmed to step from 750 nm to 390 nm in 2-nm steps, taking in data at even-numbered wavelengths, and to return, taking in data at odd-numbered wavelengths.

In both regions of the retina, four distinct cell types were identified: rods, single cones and two different classes of double cone. The rods contained a visual pigment having a wavelength of maximum absorbance (λ_{max}) 506 nm (Fig. 1), which is in

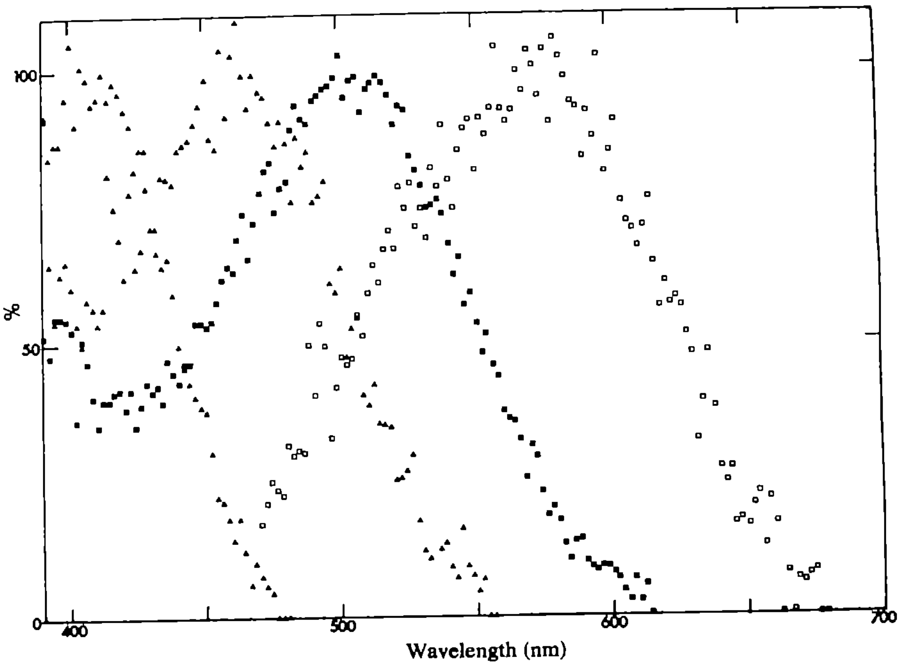

Fig. 1 Mean absorbance spectra for four classes of photoreceptor from dorsal and ventral retinal samples for three individual fish. The maximum absorbance (λ_{max}) values of the four classes are: single cone, 409 nm ($n = 13$); rod, 506 nm ($n = 9$); middle-wave-sensitive member of double cone, 463 nm ($n = 4$); long-wave-sensitive member of double cone, 576 nm ($n = 6$). Each point represents the average of values obtained at two adjacent wavelengths, one value recorded in the descending scan, the other in the ascending scan. The mean spectra have been normalized to a maximum of 100%. For each absorbance spectrum, the approximate wavelength of peak absorbance was estimated and each of 25 individual values on either side of the provisional peak was referred to the appropriate nomogram to estimate the wavenumber of peak sensitivity; this operation involves determining where the nomogram must be located on the wavenumber abscissa to yield the absorbance value under consideration. The nomograms used were the Dartnall A_1 nomogram[13] for the rods, the frog green rod nomogram[10] for the single cones and the P463 cones, and the rhesus monkey red cone spectrum[17] for the P576 cones. For the short wave-sensitive cones, the maximum absorbance was estimated using 20 points on the right-hand side only of the provisional peak.

0028–0836/82/260062—03$01 00

agreement with that given by Schwanzara[12] for an extract of the visual pigment of *Anableps*. The single cones contained a pigment maximally sensitive to short wavelengths (λ_{max} = 409 nm), while the double cones contained two pigments absorbing at longer wavelengths, with maximum absorbances of 463 nm and 576 nm. One class of double cone contained only the long-wave-sensitive pigment in both members, whereas the other class contained both the middle- and long-wave-sensitive pigments (Fig. 1). The shape of the absorbance spectra of the rods was well fitted by a Dartnall nomogram[13], which suggests that the pigment was probably based on vitamin A_1.

Ellipsosomes similar to those described by MacNichol *et al.*[14] but termed 'oil droplets' by Borwein and Hollenberg[5] were found in the ellipsoid region of the inner segment of the cones. The ellipsosomes in the double cones did not contain carotenoids, as found in birds and reptiles[15], but contained a pigment whose spectrum closely resembled that of reduced cytochrome *c*, with an intense short-wavelength absorbance band (λ_{max} = 415 nm) and two less intense absorbance bands at longer wavelengths (519 and 549 nm) (Fig. 2). The ellipsosomes of the double cones in which both members contained the 576-nm pigment (P576) were identical, with the short-wave absorbance band having a maximum density of ~0.3. A similar absorbance spectrum was measured for the ellipsosomes of the long-wave-sensitive member of the other class of double cone, but in the spectrum of the ellipsosomes of the members containing the P463, the density of the pigment was considerably greater, with a short-wave absorbance of ~0.5. Ellipsosomes were visible in the inner segments of the single cones sensitive to short wavelengths, but contained no detectable pigment.

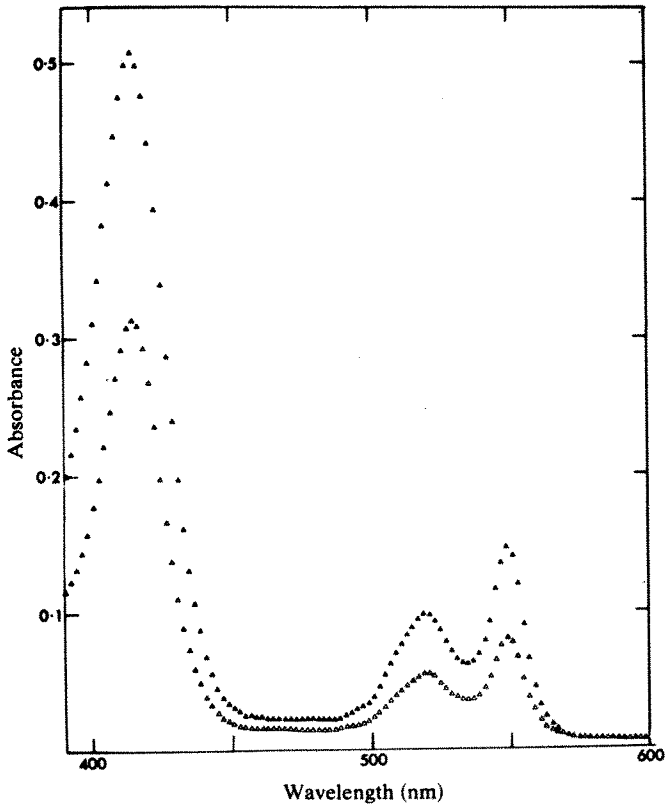

Fig. 2 ▲, Mean absorbance curve of six ellipsosomes from the P463 members of double cones and △, mean absorbance curve of seven ellipsosomes from the P576 members of double cones. The wavelengths of peak absorbance are 415, 519 and 549 nm.

As light must pass through the ellipsosomes to reach the photosensitive outer segment, it has been suggested that the ellipsosome acts as an intracellular colour filter[14]. The principal effect would be to filter a narrow band of violet–blue light (400–430 nm) from the outer segment. Making reasonable assumptions for the end-on absorbance of the cone outer segments, it is possible to construct relative spectral sensitivity functions for the different cone types (Fig. 3). It is clear that the filtering by the ellipsosomes narrows the short-wave limb of the visual pigment spectrum, particularly that of the P463 member of the double cone. This results in the P463 member of the double cone having a rapidly decreasing sensitivity from 460 nm to 420 nm, whereas the P409 single cones have a rapidly increasing sensitivity in the same region of the spectrum. This invites speculation as to possible neural interaction between these cone types which would confer increased wavelength discrimination in the short-wave region of the spectrum.

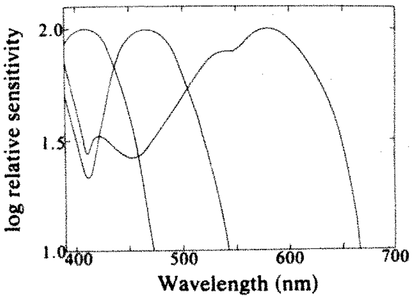

Fig. 3 Log relative sensitivity functions for the three classes of cone. These were derived by determining the absorptance spectrum for each class of cone and subtracting from this the mean absorbance spectrum of the ellipsosomes found in the inner segments of the corresponding cone type. In the case of the single cones, the sensitivity function is the same as the absorptance spectrum, as the ellipsosomes in these receptors are spectroscopically clear. The absorbance spectrum of a given class of cone (that is, the ratio of absorbed to incident light for a beam passing axially through the receptor) was calculated assuming an end-on absorbance of 0.25. The cone outer segments were ~6–10 µm long but appeared to be broken at the tips, and we have taken the true outer segment length to be ~15 µm. The specific absorbance of the cells was ~0.15, similar to values reported for other cones containing pigments based on vitamin A_1 (ref. 10).

The Cyprinodontidae (flagfish, minnows) and the Poecilidae (mollies, guppies) are closely related to the Anablepidae, all being members of the Order Microcyprini. The visual pigments of these families are very similar to those of *Anableps*; they too have violet-sensitive single cones, middle- and long-wave-sensitive double cones, and ellipsosomes in the double cone inner segments[16]. They also occupy a similar habitat in that they are all found very close to the surface in freshwater, and they are strongly diurnal and primarily surface feeders.

Although there seems to be no difference in the visual pigments in the two halves of the retina in *Anableps*, it cannot be excluded that the dorsal region may be more red-sensitive than the ventral region, either as a result of an uneven distribution of the various cone types in the two halves of the retina, or due to neural interaction giving prominence to the long wave-sensitive double cones.

Serotonin alters the phosphorylation of specific proteins inside a single living nerve cell

José R. Lemos, Ilse Novak-Hofer & Irwin B. Levitan*

Friedrich Miescher-Institut, PO Box 273, CH-4002 Basle,
Switzerland

The large size and ready identifiability of molluscan neurones have made it possible to investigate the hypothesis[1,2] that cyclic AMP-dependent protein phosphorylation may regulate neuronal electrical properties. For example, it has been found recently that intracellular application of the catalytic subunit of cyclic AMP-dependent protein kinase can alter the electrical activity of various molluscan neurones (refs 3, 4; J. De Peyer, H. Reuter and I.B.L., unpublished). We have recently demonstrated[5] that injection of a specific protein kinase inhibitor into identified *Aplysia* neurone R15 blocks the increase in K^+ conductance normally elicited in R15 by serotonin[6], implicating protein phosphorylation in the regulation of a specific ion channel by a neurotransmitter. We report here attempts to identify phosphoproteins which may be involved in such regulation, by measuring protein phosphorylation in R15 following the intracellular injections of $\gamma[-^{32}P]$ATP. The results indicate that we can indeed measure protein phosphorylation inside an individual living nerve cell, and that the extent of phosphorylation of several proteins in R15 is influenced by serotonin.

Previous attempts to measure protein phosphorylation in individual molluscan neurones have been carried out by incubating ganglia with $^{32}P_i$, then isolating nerve cell bodies and analysing the radioactive phosphoproteins[7–11]. These studies suffer from the major disadvantage that the cell body of interest can never be isolated entirely free of glia and portions of neighbouring neuronal cell bodies which contribute to the labelling pattern. Furthermore, only the cell body, and not the axonal and dendritic processes in the neuropile, is sampled by this procedure. We have circumvented these problems by developing techniques for the injection of 10^5–10^6 c.p.m. of $[\gamma-^{32}P]$ATP into neurone R15, and have analysed the radioactive phosphoproteins produced. To examine the distribution of the radioactivity in the abdominal ganglion, we have fixed and sectioned ganglia following such injections, and have examined the sections by autoradiography. The results (not shown) demonstrate that all the radioactivity is restricted to R15. Thus, when the entire abdominal ganglion is analysed by gel electrophoresis, all the radioactive phosphoproteins originate from R15's soma and neuropile processes. R15 is voltage-clamped throughout the labelling period, so changes in the phosphorylation profile in the cell can be related to changes in membrane conductance. In addition, voltage-clamping assures that changes in phosphorylation are due directly to the effects of serotonin rather than to changes in the cell's spontaneous activity induced by serotonin.

Of the total radioactivity injected into neurone R15, ~2% was incorporated into trichloroacetic acid-insoluble, chloroform/methanol-washed material during the following 50 min ($1.9 \pm 0.6\%$ in control ($n = 14$) cells, $2.1 \pm 0.8\%$ in serotonin-treated ($n = 12$) cells; not significantly different). Analysis of this material, after partial acid hydrolysis, using two-dimensional high-voltage thin-layer electrophoresis[12] shows that only two amino acid residues are phosphorylated, the major one being phosphoserine and the minor one phosphothreonine. This further substantiated that the extracted material was phosphoprotein. The polyacrylamide gel autoradiogram in Fig. 1 and the densitometric scans in Fig. 2

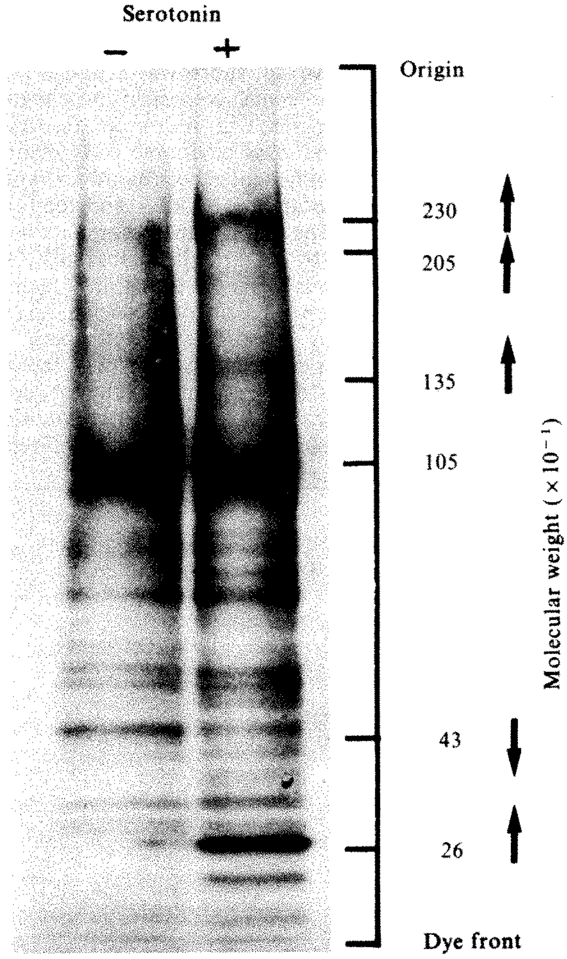

Fig. 1 Analysis of proteins phosphorylated in living neurone R15. Immediately before each experiment, $[\gamma-^{32}P]$ATP (Amersham; >5,000 Ci $mmol^{-1}$) was concentrated in an Eppendorf microfuge tube, using a rotary evaporator, to a final concentration of 1 $\mu Ci\ nl^{-1}$. For storage the $[\gamma-^{32}P]$ATP was rediluted to a concentration of 50 $mCi\ ml^{-1}$ in H_2O and was kept at −20 °C. With this protocol the ATP preparation could be used several times without substantial radiolytic decay. Using a Hamilton syringe, ~50 nl of the concentrated ATP solution were placed in the tip of a microelectrode pulled from 'Microstar' capillary tubing (Radnoti Glass). Electrodes were used within minutes of filling, again to avoid substantial radiolytic decay and/or blockage of the electrode tip. ATP solution (0.5–2.0 nl; estimated by movement of the meniscus in the electrode tip) was injected into voltage-clamped neurone R15 (estimated cell body volumes 20–60 nl) under pressure. Analysis of the material remaining in the electrode tip after the injection indicated that >85% of the radioactivity was still in ATP. The total amount of ATP injected (0.1–0.4 pmol) was ≤1% of the endogenous level in R15 (D. Weinreich, personal communication). These ATP injections did not alter the current–voltage relationship of R15. The ganglion was first perfused with normal *Aplysia* saline for 30 min and then with either normal *Aplysia* saline or saline containing 5 μM serotonin for an additional 20 min. Serotonin produces a large increase in K^+ conductance in this time[5,6]. Cells were voltage-clamped throughout, and only those exhibiting normal current–voltage characteristics and normal responses to serotonin were taken for analysis. Fifty minutes after injection the entire abdominal ganglion was frozen in liquid N_2, and homogenized in 1 ml of ice-cold stop buffer (50 mM MOPS, *p*H 7.0, 20 mM EDTA, 10 mM NaF, 1 mM ATP). The connective tissue sheath remained essentially intact and was discarded. Two ml of 20% trichloroacetic acid (TCA) was added to the homogenates at 4 °C. The resulting precipitates were collected by centrifugation, washed twice with 10% TCA, then twice with chloroform/methanol (1:2 then 2:1, v:v) to extract phospholipids. The pellets were redissolved in 100 μl of sample buffer (100 mM dithiothreitol, 80 mM Tris-HCl, *p*H 6.8, 2% SDS, 10% glycerol). Samples were boiled for 2 min and run on an SDS-polyacrylamide gradient (5–17.5% acrylamide) slab gel[13]. In this experiment, the control (−serotonin) track was loaded with 11,600 c.p.m., incorporated following an injection of 360,000 c.p.m. of $[\gamma-^{32}P]$ATP into R15; the +serotonin track contained 18,000 c.p.m. (600,000 c.p.m. injected). Following electrophoresis the gel was dried and autoradiographed using Kodak X-Omat X-ray film for 7 days. The resulting autoradiogram exhibits at least 15 phosphoprotein bands originating from within R15. ↑↓, Bands whose phosphorylation state was significantly increased or decreased, respectively, by serotonin (see Table 1).

---

*Present address: Graduate Department of Biochemistry, Brandeis University, Waltham, Massachusetts 02254, USA.

Table 1 Relative incorporation into individual phosphoprotein bands

M_r	% Of total radioactivity Controls ($n = 8$)	Serotonin ($n = 8$)	Mean % change
230,000	4.1±0.3	6.9±1.0	+69*
205,000	7.5±0.5	10.3±1.1	+41*
135,000	8.2±0.5	10.6±0.7	+29*
105,000	19.7±1.5	20.2±1.6	+2
82,000	8.7±0.6	8.6±0.7	−1
68,000	11.8±0.8	13.1±1.1	+12
50,000	8.8±0.5	8.8±0.3	0
43,000	5.0±0.2	4.1±0.2	−21*
36,000	4.4±0.5	4.2±0.6	−5
31,000	3.9±0.8	2.7±0.3	−30
26,000	3.5±0.3	5.9±0.5	+55*
22,000	5.8±1.2	3.6±0.4	−31

Densitometric scans of autoradiograms (for example, Fig. 2) were used to quantify the relative amount of radioactivity in individual phosphoprotein bands. Areas under each peak were computed as a percentage of the total area of the scan; thus, the numbers in the table represent the radioactivity in each band as a percentage (means ± s.e.m.) of the total radioactivity in the gel. Experiments performed on the same day were paired and Student's t-test used to evaluate the differences (expressed here as mean % change) between control and serotonin-treated ganglia. Although the 31,000- and 22,000-M_r proteins showed large mean per cent changes, they also exhibited large variability (see, for example, Fig. 2) and thus these changes were found not to be significant ($P > 0.6$).

*Changes induced by serotonin which were significant ($P <$ 0.02–<0.007).

demonstrate that at least 15 phosphoproteins, of molecular weights (M_rs) 22,000–230,000, were labelled in R15 during the 50 min following injection of [γ-^{32}P]ATP. When serotonin was added to the medium bathing the abdominal ganglion during the last 20 min of the labelling period, there was a large increase in K^+ conductance in R15[5,6], and a change in the extent of labelling of several phosphoproteins. This number of changes is not surprising because serotonin increases cyclic AMP levels in this cell[6] and this could lead to a variety of changes in the phosphorylation state of many intracellular proteins. The phosphorylation of several high molecular weight proteins (M_rs 230,000; 205,000; 135,000) and of a 26,000-M_r protein was increased significantly in the presence of serotonin (Figs 1, 2; Table 1). In addition, there was a decrease in the phosphorylation of a 43,000-M_r band (Figs 1, 2; Table 1).

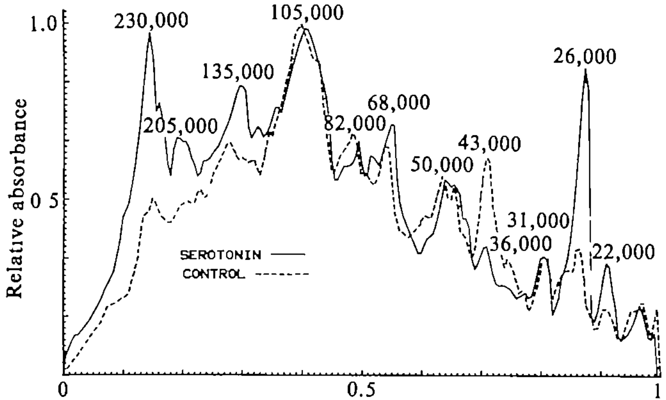

Fig. 2 Densitometric scans of the autoradiograms shown in Fig. 1. Autoradiograms were scanned using a Joyce-Loebl densitometer. The scanner was centred on each gel track, and the scan width was set at maximum to average the density across the entire track. Because the 105,000-M_r peak was not affected by serotonin (see Table 1), we normalized the scans to the height of this peak to facilitate visualization of the specific effects of serotonin. This analysis permits the evaluation of changes in labelling of specific phosphoproteins independent of differences in total incorporation from one cell to another ———, Serotonin; · · · · · ·, control.

There is only limited information on protein phosphorylation in the *Aplysia* nervous system. Although our early studies[7,8] (recently confirmed by Paris *et al.*[10]) indicated that serotonin could influence the phosphorylation state of a high molecular weight protein, it is not clear whether it is related to the 135,000-M_r protein described here. The present experiments indicate that, in addition to this phosphoprotein, the phosphorylation of several other proteins in R15 can be influenced by serotonin. This *in vivo* approach should permit an analysis of the possible role of these phosphoproteins in the regulation of K^+ conductance in this cell.

We thank Dr A. Matus and Mr M. Ackermann for help with the sectioning and autoradiography, Mr J. Maeder for computer programming and Dr J. Martin-Pérez for analysing the phosphoamino acids.

The growth hormone release-inhibiting factor somatostatin was originally isolated and characterized from hypothalamic extracts[1]. Avian pancreatic polypeptide (APP) was first isolated from chicken pancreas[2]. Using antibodies raised against these peptides, both somatostatin-like[3–5] and APP-like[6,7] immunoreactivities have been found in many regions of the nervous system, and the peptides have been shown to coexist with catecholamines or other neuropeptides in certain neuronal systems[8–11]. In particular, we have recently reported that some neurones in the rat telencephalon contain both somatostatin- and APP-like immunoreactivities[12]. We present here immunohistochemical evidence that in the human cerebral cortex also, some neurones contain both immunoreactivities.

Specimens of human frontal, temporal and cingulate cortex were obtained from patients undergoing lobe resection as a treatment for glial tumours. Small pieces (about 10 × 5 × 2 mm) of cortex of normal appearance were taken from cortical areas, located as far as possible from the pathological area, immediately after the lobe was resected. The specimens were immersed in ice-cold 10% formalin in 0.1 M phosphate buffer for 2–6 h. The time between occlusion of the blood supply to the cortex and the immersion of the tissue was ~30 min. After fixation

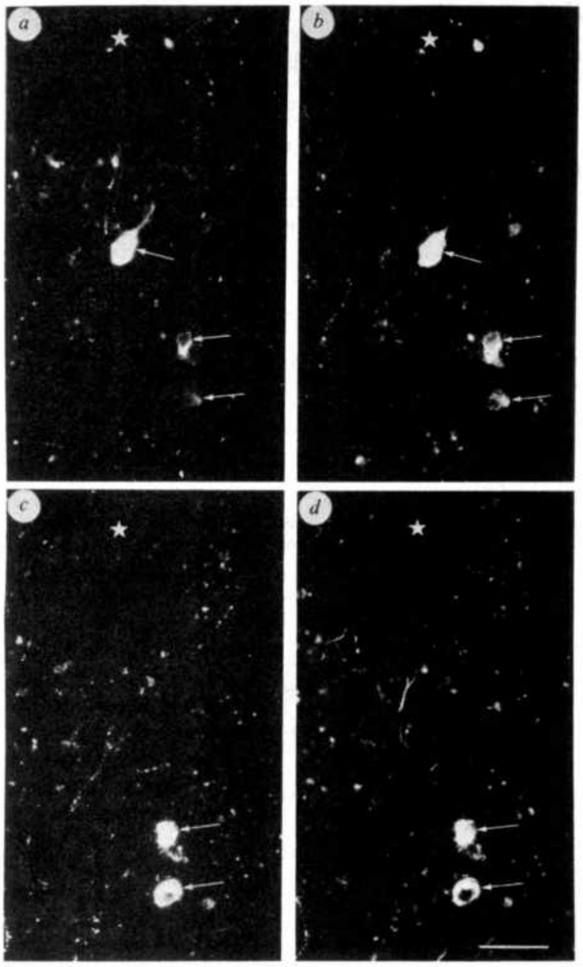

Fig. 1. *a–d*, Immunofluorescence micrographs of 10 μm thick sections of the human neocortex after incubation with antisera to somatostatin (*a*, *d*) or APP (*b*, *c*). *a* and *b*, The same section stained initially for somatostatin (*a*), then eluted according to Tramu *et al.*[16] and restained with antibodies against APP (*b*). *c*, *d*, The same section, which is adjacent to that shown in *a* and *b*, first stained for APP-like immunoreactivity (*c*), then eluted[16] and restained for somatostatin (*d*). Arrows indicate neurones that contain both somatostatin- and APP-like immunoreactivities, in either the serial section or the restaining experiments. ☆, A blood vessel. Scale bar, 50 μm for *a–d*.

the tissues were rinsed in 0.1 M phosphate buffer containing 5% sucrose for at least 24 h. Sections were then cut on a cryostat (Dittes) and processed according to the indirect immunofluorescence technique of Coons and collaborators[13,14].

Alternate 10 μm thick sections of cortex were incubated overnight at 4 °C with antisera raised in rabbits against APP[7,12] or somatostatin[15]. Both sera were diluted 1:100 in 0.1 M phosphate buffer containing 0.3% Triton X-100. After rinsing, the sections were incubated with fluorescein isothiocyanate (FITC)-conjugated swine anti-rabbit IgG (Dako), rinsed, coverslipped and examined in a Zeiss fluorescence microscope.

In further experiments, sections that had been stained for one neuropeptide were photographed, then the initial antiserum was eluted with 0.1% $KMnO_4$ in 0.2% $H_2S_2O_4$ for 30 s and the sections decolorized in 0.5% $Na_2S_2SO_5$ for 15 s (ref. 16). The sections were then incubated in the FITC-conjugated IgG and examined in the fluorescence microscope. If no staining was observed at this stage, indicating that the first antibody had been successfully eluted, the sections were then incubated with antibody to the other neuropeptide, followed by the FITC-conjugated IgG and once more examined in the microscope and photographed. Using this procedure the same section could be sequentially stained for somatostatin- and APP-like immunoreactivities.

Antisera incubated with an excess of the respective neuropeptide (50 μg of synthetic somatostatin or APP per ml antiserum diluted 1:10) served as controls. Preabsorption of the somatostatin antibody with APP or of the APP antibody with somatostatin had no effect on the resultant staining pattern. This indicates that none of the sera used in these experiments recognizes both peptides.

In sections incubated with antisera to APP, we observed a dense network of immunoreactive fibres. In specimens cut perpendicular to the cortical surface, a definite pattern of fibres could be discerned. In cortical layers II–VI, most of the APP-positive fibres appeared to run vertically out from the deeper layers towards the surface, although many fibres branched laterally as well. In contrast, in layer I, most of the APP-positive fibres ran parallel to the cortical surface; however no fibres were seen in the outer 50 μm of cortex. This staining pattern was observed in frontal, temporal and cingulate cortex specimens.

In sections incubated with anti-somatostatin antisera, the pattern of fibres observed was similar to that described for APP. The somatostatin-positive fibres fluoresced much more weakly, however, and, in particular, the fibres running parallel to the cortex in layer I were much less heavily stained.

Many immunoreactive cell bodies were observed in the cortex following incubation of the sections with either APP or somatostatin antisera. The cells were scattered throughout layers II–VI, and were also commonly found in the subcortical white matter. The cells were pyramidal, bipolar, round or multipolar in shape, with dendrites spreading out in all directions.

In serial sections stained alternatively for APP or somatostatin, we often found that one portion of a cell was positive for APP in one section while in a second section, the other portion was positive for somatostatin (Fig. 1*a*,*c*). This indicates that a single cell can contain both neuropeptides. Examples of this were found in all cortical layers except layer I.

The coexistence of somatostatin- and APP-like immunoreactivities in a cortical neurone was also frequently demonstrated in the elution–restaining experiments. Using this protocol, we found neurones that first stained for somatostatin (Fig. 1*a*) and then, after elution, restained for APP (Fig. 1*b*), and cells that were first shown to be APP positive (Fig. 1*c*) and, after elution and restaining, also seen to contain somatostatin immunoreactivity (Fig. 1*d*).

The occurrence of more than one neuroactive substance in a single neurone has recently been reviewed[17,18]. The phenomenon was first observed in invertebrates, but has since also been observed in mammalian neurones, and now in human brain.

We have shown that the coexistence of somatostatin and APP reported here is not due to cross-reactivity of the antisera. Also, larger presumed precursor molecules have been found for both peptides[19–22] and they seem quite distinct. This and the clear differences in the distribution of the peptides in other brain regions[12] suggests that they do not have a common precursor and that their coexistence is a special property found only in certain cell types.

The coexistence of somatostatin- and APP-like peptides within a selective population of neurones suggests that they both may function as transmitters or modulators of neural information. In this regard, somatostatin has been found to have potent electrophysiological effects on cortical neurones[23–25] and both calcium-dependent release[26,27] and high-affinity binding[28] of somatostatin have been demonstrated in mammalian brain. APP has also been found to have postsynaptic actions[29]. Thus the presence of these two neuroactive substances in a single cortical neurone may allow the cell to transmit more than one message to its postsynaptic targets.

Recently somatostatin levels have been found to be reduced in the cerebrospinal fluid of patients with Huntington's disease[30]. Also, cortical somatostatin levels are markedly reduced in Alzheimer's disease and in senile dementia of Alzheimer type[31,32]. This suggests that a loss of forebrain somatostatin neurones may be a symptom of these diseases. As an APP-like peptide is contained in many forebrain somatostatin cells, these diseases are probably also associated with a loss of APP-like immunoreactivity. The role of cortical neurones containing both somatostatin- and APP-like immunoreactivity in these conditions remains to be determined.

We thank Ms Annika Edin, Ms Anne Peters and Ms Waldtraut Hiort for technical assistance and Ms Birgit Frideen for secretarial help. This work was supported by grants from the Swedish MRC (04X-2887), Magnus Bergvalls Stiftelse and Knut and Alice Wallenbergs Stiftelse. S.R.V. is a fellow of the Canadian MRC.

Fission-spectrum neutrons at reduced dose rates enhance neoplastic transformation

C. K. Hill, F. M. Buonaguro*, C. P. Myers*, A. Han & M. M. Elkind*

Mammalian Cell Biology Group, Division of Biological
and Medical Research, Argonne National Laboratory, Argonne,
Illinois 60439, USA

We have studied the effect of reduced dose rates of radiation on neoplastic transformation using the C3H/10T1/2 mouse embryo-derived cell line developed by Reznikoff *et al.*[1]. In this cell system, transformation can be measured by scoring the foci of piled-up cells that occur after the loss of contact inhibition of growth. We report here that reduction of the dose rates of fission-spectrum neutrons (of mean energy 0.85 MeV) from 38.5 or 10.3 to 0.43 and 0.086 rad min^{-1} has no effect on cell killing but increases transformation frequency. These data are in contrast to previously published results obtained with ^{60}Co γ rays where reduction of the dose rate resulted in a marked reduction in transformation frequency[2,3]. Although cancer induction in man involves many factors besides those at the cellular level, the implication from our findings is that the risk of cancer induction due to work-related exposure to neutrons in the nuclear power industry may be greater than previously thought.

Cell cultures were grown at 37 °C in plastic T-flasks, or in plastic 100-mm Petri dishes, in Eagle's basal medium (Gibco) supplemented with 10% heat-inactivated fetal calf serum (Reheis Chemical Co., Illinois) according to methods previously described[2–5]. The JANUS reactor of the Division of Biological and Medical Research, Argonne National Laboratory, was used to expose cells to fission-spectrum neutrons[5]. A special incubator, made of light plastic and styrofoam to minimize any changes in the quality of the neutron beam, was used for the low dose rate exposures at 0.43 and 0.086 rad min^{-1}, and the cells were kept at 37 °C while attached in plastic T-flasks containing Eagle's supplemented medium. In all experiments, irradiated cells were removed from the incubator after exposure, trypsinized, plated out in Petri dishes and placed in conventional incubators for the 6 weeks necessary for transformed foci to develop[1,5]. In a control experiment, cells were grown in the special incubator without irradiation. No transformed colonies were observed for these controls; that is, the transformation frequency per surviving cell was $<8.7\times10^{-5}$. Dosimetry was performed inside the incubator at the position of the cells[5]. High-dose rate irradiations (38.5 or 10.3 rad min^{-1}) were carried out at room temperature[5]. Transformed foci were scored as previously described[1,5] and transformation frequencies per surviving cell were calculated according to Han and Elkind[5].

Consistent with the earlier results of Sinclair[6] with V79 Chinese hamster cells, the data in Fig. 1 show no significant variation in cell killing after a reduction in the fission-spectrum neutron dose rate from 38.5 to 0.086 rad min^{-1} (5.2 rad hr^{-1}) even though the cells were irradiated in optimal growth conditions. The lowest dose rate used here was 20-fold less than that previously reported[6,7]. At 0.086 rad min^{-1}, cells undergo one

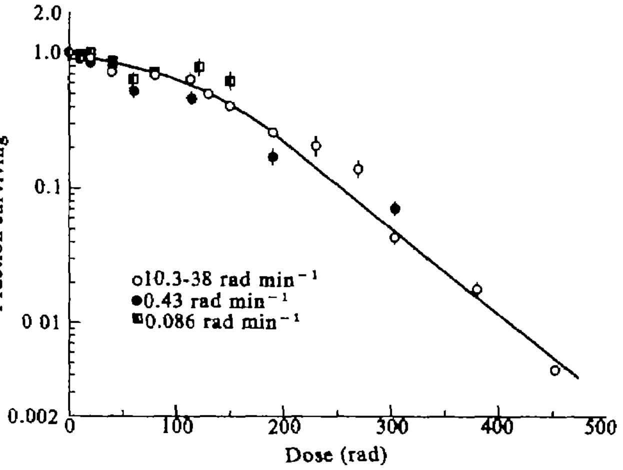

Fig. 1 The survival of 1OT1/2 cells exposed to fission-spectrum neutrons from the JANUS reactor at the Argonne National Laboratory. The line is drawn through the average surviving fractions from all experiments performed over a 3-yr period. The individual data points shown at high and at low dose rates were obtained concurrently as part of this study; the doses refer to the integrated exposures of populations of cells. Cells in growth medium were exposed at 37 °C and immediately after exposure were suspended by trypsinization and plated for survival. Plating efficiency = 21–42%, multiplicity ~ 1. Bars represent standard errors[5].

A survival curve based on averages of the data from all experiments (Fig. 1) was used to estimate surviving fractions for the exposures at 10.3–38.0 rad min^{-1}. For the low-dose rate exposures, surviving fractions are those determined from the same population used to estimate the transformation frequency. Details of the λ calculation and its standard error are given in ref. 5. λ, The average number of transformed foci per dish, was computed from the proportion of dishes free of transformed colonies, f, by $\lambda = -\ln f$. Transformation frequency = λ/number of surviving cells per dish. Controls, that is, unirradiated cells, represent the cumulative data from the transformation experiments reported for this and other studies[2–5].

* Number corrected for plating efficiency of unirradiated cells and surviving fraction per 90-mm plastic Petri dish.

† Total number of type 2 and 3 transformed foci[1,5].

or two divisions during exposure, depending on the length of exposure. However, flow cytofluorographic analyses of the DNA content of the cells in each sample, using an Ortho Instruments 2150 system, indicated that no significant perturbation in distribution of cell cycles occurred until 150 rad had accumulated at 0.43 rad min^{-1}, or 100 rads at 0.086 rad min^{-1}. Thus, it is unlikely, especially at the smaller doses, that our results were significantly affected by changes in cell-cycle distributions during exposure.

There was no apparent reduction in transformation frequency when the dose rate of fission-spectrum neutrons was reduced by a factor of 200 (38.5 to 0.086 rad min^{-1}). Indeed, whereas at higher doses the high and protracted dose rates seemed to induce the same transformation frequency, at 10–70 rad there was a significant enhancement of transformation frequency for dose rates of 0.43 and 0.086 rad min^{-1}. The data for transformation at high dose rates in Fig. 2 are a combination of those previously published[5] and those obtained in the present series of experiments; the two sets of results did not differ significantly and therefore were pooled. Table 1 summarizes the results plotted in Figs 1 and 2.

Although cells apparently are unable to repair sublethal damage when exposed to the JANUS reactor beam at reduced dose rates, consistent with earlier studies performed with the same beam using fractionation of high dose-rate exposures[8,9], the enhanced transformation shown in Fig. 2 is unexpected. Han and Elkind[5] showed that the fractionation of high dose-rate exposures of neutrons from the JANUS reactor had little if any effect on transformation frequency per surviving cell. Figure 2 shows that reduced dose rates significantly enhance transformation in the low dose region from 10–70 rad, with no concomitant effect on survival (Fig. 1).

To illustrate further the qualitatively unexpected nature of our transformation results, Fig. 3 compares the ratios of transformation frequencies per survivor at low to high dose rates for neutrons from the JANUS reactor and for ^{60}Co γ rays[3]. Clearly, the reduced dose rates of γ-ray irradiation, in the 0–100 rad region, are less effective than high dose rates, while for the same dose interval, low dose rates of fission-spectrum neutrons are appreciably more effective than high dose rates. Furthermore, few if any of the changes in transformation frequency can be attributed neither to differential cell killing, in view of the small amount, and dose rate independence of lethality in this dose range (Fig. 1), nor to parasynchronous effects as already noted.

There are some indications, primarily from results obtained with *in vivo* systems[10–13], that low dose rates of fission-spectrum neutrons may be more effective at producing tumours than high dose rates. However, interpretation of the results following whole-body exposures is complicated by the interactions among different tissue and organ systems (for example, see Fry[12] in reference to the induction of Harderian gland tumours). Our results, obtained with actively growing mammalian cells in culture, show that enhanced induction rates of neoplastic transformation could be due to intracellular events in the target cells themselves. A similar specificity applies to the observation that reduced transformation frequencies due to low dose rates of ^{60}Co γ rays result from repair processes in the target cells[3].

Finally, we may draw from our data several inferences about mechanisms. Compared with γ rays, fission-spectrum neutrons may be considered a high linear energy transfer (LET) radiation. The shoulder on the neutron survival curve indicates that accumulation of sublethal damage contributes to cell killing and that such damage is not repaired, in contrast to the repair of sublethal damage from γ rays observed for prolonged exposure[3]. As an acute dose of fission-spectrum neutrons does not prevent the repair of the damage that is additive to X-ray-induced sublethal damage[8], we infer that different targets are affected by high as opposed to low LET radiation and that the damage (or the target) responsible for neutron-induced killing cannot be repaired. With respect to transformation, we note that, at reduced dose rates of γ rays, survival increases but transformation per surviving cell decreases, both relative to high dose rate exposure, and that transformation is reduced even in the dose region where cell killing is minimal. In similar exposure conditions, reduced dose rates of fission-spectrum neutrons result in enhanced transformation. Thus we infer that the repair of γ-ray-induced transformation damage has a net error-free component of repair, and that the increase in neutron-induced transformation results from a net error-prone component of repair independent from sublethal damage in view of the dose rate independence of the latter. Further experiments are in progress to determine whether the same targets are involved in transformation induced by high- compared with low-LET radiations.

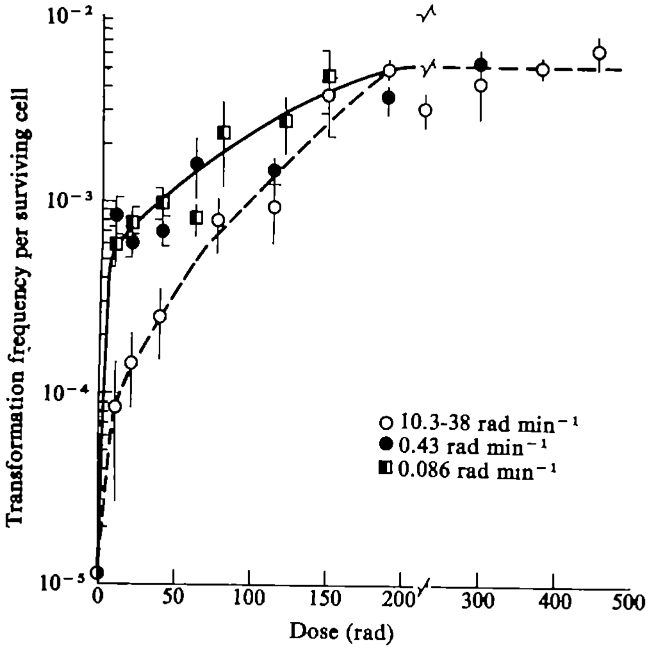

Fig. 2 Transformation frequency per surviving cell for 1OT1/2 cells exposed to fission-spectrum neutrons (data given in Table 1). The broken line represents the acute dose rate curve and the solid line indicates the data from both low dose rates used. Other details as for Fig. 1.

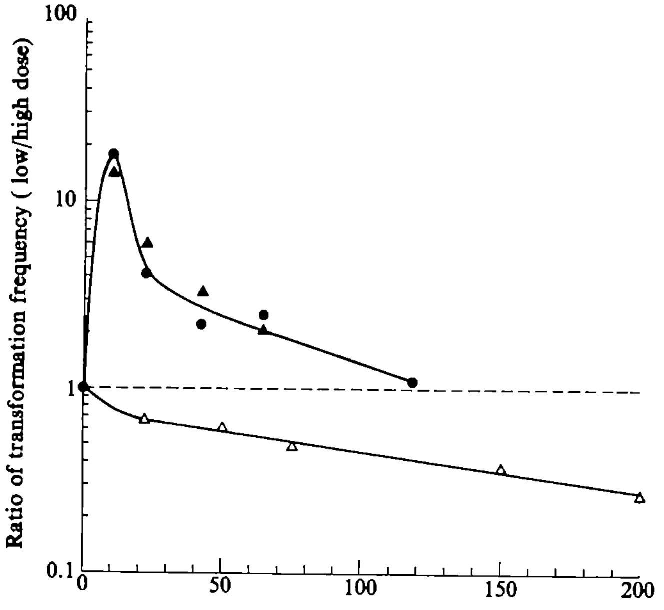

Fig. 3 The ratio of transformation frequency per surviving cell for low compared with high dose rates, obtained for 1OT1/2 cells, as a function of dose. For both fission-spectrum neutrons and ^{60}Co γ rays, the doses refer to the integrated exposures of populations of cells. Dose rate independence would plot as the broken line shown. ●, ▲ = 0.43 and 0.086 rad min^{-1}, respectively, of JANUS neutrons. △, 0.1 rad min^{-1} ^{60}Co γ rays.

Malignant transformation of human embryo retinoblasts by cloned adenovirus 12 DNA

P. Byrd, K. W. Brown & P. H. Gallimore

Cancer Research Campaign Laboratories, Department of Cancer Studies, University of Birmingham, The Medical School, Birmingham B15 2TJ, UK

Human adenoviruses can morphologically transform rodent cells *in vitro*. The transforming gene(s) resides in the early region 1 (E1) transcription unit (0–11.2 map units) at the left end of the conventional adenovirus genome[1–4]. The only adenovirus-transformed human cell line reported so far, the 293 cell line, was isolated from cell cultures transfected with sheared DNA of the non-oncogenic subgroup C adenovirus type 5 (Ad 5)[5,6]. The ability of this line to complement the growth of Ad 5 E1 mutants has facilitated the isolation of transformation-defective Ad 5 mutants[7,8]. As no oncogenic subgroup A adenovirus type 12 (Ad 12) transformed human cell lines were available for the selection of Ad 12 E1 mutants, we attempted to isolate such lines by transfecting cell cultures with a recombinant plasmid (pAsc2) which contained the Ad 12 *Eco*RI-C DNA fragment (0–16.5 map units) inserted at the *Eco*RI site of pAT153 (ref. 9). We describe here the isolation of a pAsc2-transformed human embryo retinoblast cell line that contains many copies of the Ad 12 transforming region, expresses virus-specified proteins and, following inoculation into athymic mice, forms tumours which resemble retinoblastomas.

The suggestion that Ad 12-induced rodent tumours originate specifically from primitive neural epithelium[10], together with the discovery that this virus induces retinal tumours following intraocular inoculation of rats and baboons[11,12], prompted us

0028-0836/82/260069—03$01 00

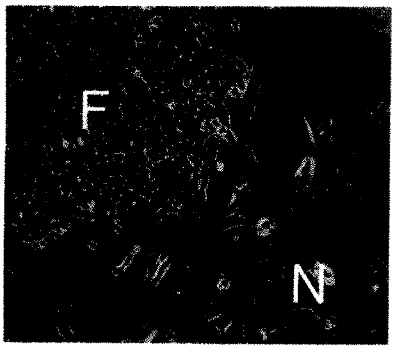

Fig. 1 An edge of a pAsc2-transformed human embryo retinoblast focus. The retinas from the eyes of an 18-week-old male fetus (therapeutically aborted) were distributed in six 50-mm tissue culture dishes and grown in RPMI medium containing 20% fetal calf serum (FCS) and antibiotics (penicillin and streptomycin, 100 units ml^{-1}). Ten days after seeding, the cultures (containing $\sim 1\times10^6$ cells per dish) were transfected with pAsc2 (10 μg per dish) using the calcium phosphate precipitation technique[25] with the glycerol boost[26]. Seventeen hours after transfection, each culture, including two control cultures which were transfected with pAT153 alone (10 μg per dish), was subcultured to four 50-mm dishes. The cells were then grown in RPMI medium containing 5% FCS and antibiotics. Only one PAsc2-transformed focus (F) was identified against the background of normal (N) cells; the experiment was terminated 10 weeks after transfection. This focus was isolated and established in a 35-mm dish and after 14 days the transformed cells were transferred to a 50-mm dish. This transformed cell line (Ad 12 HER1) was subsequently grown and passaged in 90-mm dishes at a split ratio of 1:15; the cells are maintained in RPMI containing 10% FCS and antibiotics. ×75.

to attempt to transform human embryo retinoblasts (HER cells) *in vitro* with pAsc2. Primary cultures of human retinoblasts were transfected with pAsc2, and one transformed focus, identified 45 days after transfection (Fig. 1), was isolated and established as a continuous cell line. This cell line has been designated Ad 12 HER 1 and is the first reported Ad 12-transformed human cell line. Cytogenetic analysis revealed a pseudotetraploid human karyotype. We have grown the Ad 12 HER1 cell line beyond the 36th tissue culture passage level and at no time has its growth entered a crisis phase. This is in contrast to the establishment of the 293 cell line[6].

Human embryo retinoblasts are the only human cell type we have been able to transform reproducibly with pAsc2. In two recent experiments, 10 transformed cell foci were identified in seven dishes of pAsc2-transfected HER cells (10 μg pAsc2 per 1×10^6 cells per dish); 4 of these foci were isolated and established as cell lines. The low specific transforming activity of pAsc2 on HER cells, which is an order of magnitude lower than on cultures of primary rat cells[9], is >100-fold higher than that on human embryo kidney (HEK) cells. The isolation and biological properties of the pAsc2-transformed HEK cell lines and additional pAsc2-transformed HER cell lines will be reported elsewhere (J. Whittaker, P.B. and P.H.G. in preparation).

When Ad 12 HER1 cell DNA was digested with the restriction endonucleases *Bgl*II or *Sst*I and subjected to Southern blotting analysis[13] using ^{32}P-labelled Ad 12 *Eco*RI-C DNA fragment as probe, Ad 12 sequences were found on many DNA fragments (Fig. 2, tracks 3 and 4, respectively) whose sizes

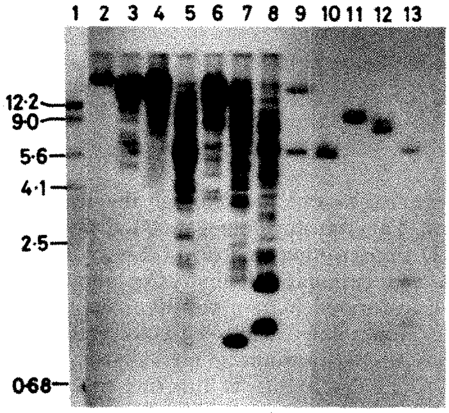

Fig. 2 Detection of Ad 12 DNA sequences in Ad 12 HER1 cell DNA. Samples (5 μg) of Ad 12 HER1 DNA were digested with restriction endonucleases, electrophoresed in a 0.8% agarose gel and subjected to Southern blotting analysis as described previously[9]. Track 1, 5 μg normal HEK cell DNA and 20 pg Ad 12 DNA (equivalent to ~0.64 copies per cell) digested with *Eco*RI; track 2, high molecular weight Ad 12 HER1 DNA; tracks 3, 4, 5, 6, 7, 8, Ad 12 HER1 DNA digested with *Bgl*II, *Sst*I, *Eco*RI, *Bam*HI, *Xba*I and *Hin*dIII respectively: tracks 9, 10, 11, 12, 13, 5 μg normal HEK cell DNA and 20 pg pAsc2 (equivalent to 2.4 copies per cell) digested with *Bgl*II, *Eco*RI, *Bam*HI, *Xba*I and *Hin*dIII respectively. Track 1 was hybridized with ^{32}P-labelled Ad 12 DNA; tracks 2–13 were hybridized with ^{32}P-labelled Ad 12 *Eco*RI-C DNA fragment. The sizes of the Ad 12 DNA *Eco*RI fragments (in kilobase pairs) are indicated. Summation of the autoradiographic bands and their intensities indicates that each Ad 12 HER1 cell contains the equivalent of ~50 copies of the Ad 12 *Eco*RI-C DNA fragment.

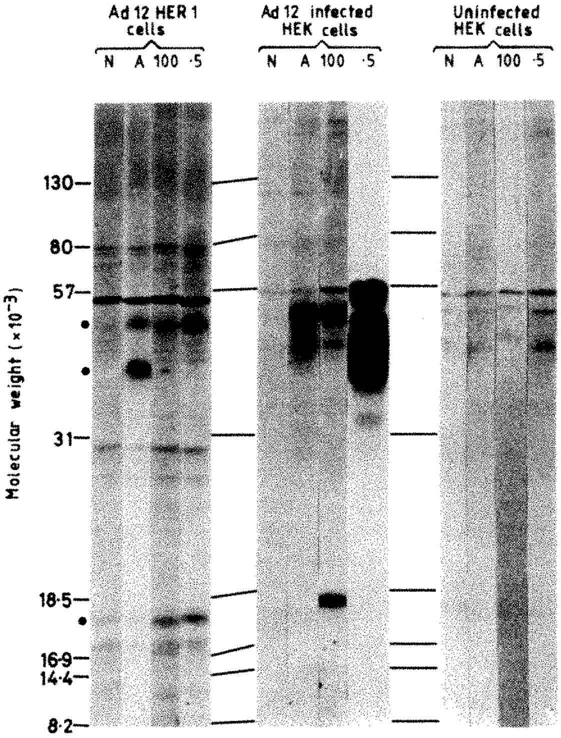

Fig. 3 Immunoprecipitation of Ad 12-specific proteins. Ad 12 HER1 cells, HEK cells or Ad 12-infected HEK cells (15 h after infection at M.O.I. of 400 plaque-forming units per cell) were preincubated in 9-cm dishes for 1 h in 3 ml of methionine-free modified Eagle's medium, containing 2% (v/v) FCS, and then labelled for 2 h in the same medium containing 100 μCi L-^{35}S-methionine (>600 Ci mmol^{-1}, Amersham). Cleared extracts were made from the labelled cells and aliquots were immunoprecipitated with normal rat serum or Ad 12 tumour-bearer serum (pAsc2 HLBRK1, Ad 12/LP/100-1 or 0.5J4) essentially as described elsewhere[27]. Immunoprecipitates were run on 10–15% gradient SDS-polyacrylamide gels[28] and ^{35}S-labelled proteins were detected by fluorography[29]. The cell extracts and tumour bearer sera are identified above the tracks; normal rat serum and rat sera raised against pAsc2 HLBRK1, Ad 12/LP/100-1 or 0.5J4 are identified as N, A, 100 and ·5 respectively. ●, Ad 12-specific proteins expressed in Ad 12 HER1 cells. The positions and sizes of molecular weight standards are indicated to the left of the tracks containing extracts of Ad 12 HER1 cells; their positions in the tracks containing extracts of uninfected and Ad 12-infected HEK cells are indicated by lines connecting to the Ad 12 HER1 tracks.

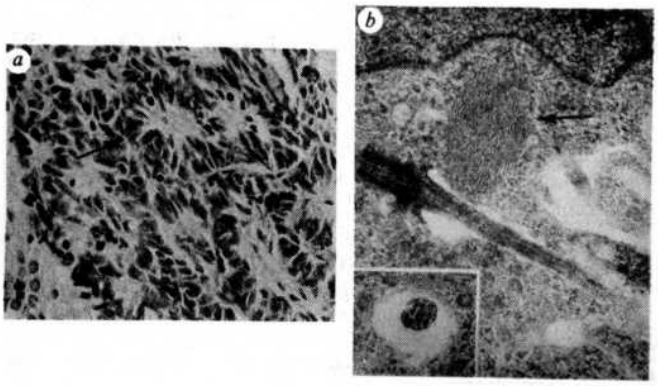

Fig. 4 *a*, Section through a cerebral tumour produced in a nude mouse following intracranial inoculation of Ad 12 HER1 cells. The arrow indicates a Homer–Wright rosette. The tumour was fixed in FAM (formaldehyde, acetic acid and methanol (1:1:8), paraffin sectioned and stained with haematoxylin–eosin. ×650. *b*, Electron micrograph of part of an Ad 12 HER1 cell showing a longitudinal section through a cilium and a multilamellar structure (arrow) which is reminiscent of the outer segment of a photoreceptor cell (×31,250). Inset, transverse section of an Ad 12 HER1 cilium showing 9+0 microtubule configuration (×75,000). Cells were fixed in 1% glutaraldehyde and post-fixed with 1% osmium tetroxide. Sections were stained with uranyl acetate and lead citrate.

ranged from >12 kilobase pairs (12 kb) to 2.2 kb. As these enzymes cleave host DNA sequences only, each fragment represents a separate insert of pAsc2 sequences. DNA fragments which co-migrated with the Ad 12 *Eco*RI-C DNA fragment and linear pAT153 DNA (data not shown) following digestion of Ad 12 HER1 DNA with *Eco*RI (Fig. 2, track 5) produced intense autoradiographic bands. This suggests that Ad 12 HER1 cells contain intact, integrated copies of the viral and vector sequences and it is likely that some of the inserts contain tandem repeats of the entire recombinant plasmid. The Ad 12 and Ad 12–pAT153 DNA fragments expected from digestion of pAsc2 by *Eco*RI, *Bam*HI, *Hin*dIII or *Xba*I were all identified in Ad 12 HER1 DNA following digestion with these enzymes (Fig. 2, tracks 5, 6, 7, 8). In addition, other fragments were identified which contained both Ad 12 DNA and pAT153 or these DNA species independently. The structures of these fragments, ranging in size over >12–0.63 kb, have not been determined.

^{35}S-methionine-labelled extracts from Ad 12 HER1 cells or HEK cells collected 18 h after infection by purified Ad 12 virus were immunoprecipitated using Ad 12 tumour-bearer rat sera. The sera were raised against tumorigenic cell lines that expressed proteins from Ad 12 early region 1 and other early regions (0.5J4)[14] or from E1 only (Ad 12/LP/100–1 (ref. 15) and pAsc2 HLBRK1 (ref. 9)). Polypeptides with molecular weights of 52,000 (52K), 41K and 18K were detected (Fig. 3) and as they were not immunoprecipitated from extracts of uninfected HEK cells, must be authentic Ad 12-specified proteins. Therefore, Ad 12 HER1 cells express proteins which are known to be encoded within the Ad 12 E1 transcription unit[16,17].

The tumorigenic potential of Ad 12 HER1 cells has been ascertained by inoculating 6–10-day-old congenitally athymic nude mice. Subcutaneous inoculation of 5×10^6 Ad 12 HER1 cells at the fifth, sixth and seventh tissue culture passage levels resulted in tumours at the site of inoculation in 1/7, 1/5 and 1/6 injected animals respectively, with latent periods of 73–89 days. However, all animals (4/4) injected intracranially with as few as 1×10^4 cells at the eighth passage died from cerebral tumours with a mean time to death of 75 days. Thus, Ad 12 HER1 cells are highly tumorigenic when inoculated intracranially. Histological analysis of Ad 12 HER1-induced tumours showed them to consist of clusters of small cells with many mitotic figures. Homer–Wright rosettes and incomplete rosettes were frequently seen (Fig. 4*a*); these rosettes and Flexner–Wintersteiner rosettes are characteristic of poorly differentiated human retinoblastomas[18].

Electron microscopic analysis occasionally revealed cilia with 9 + 0 microtubule configuration on Ad 12 HER1 cells (Fig. 4*b* and inset). This configuration is characteristic of cilia of normal human retinal photoreceptor cells and retinoblastoma cells[19] and has also been observed in cilia of Ad 12 virus-induced retinal tumours of the rat and baboon[11,12]. In Ad 12 HER1 cells we also observed oval membranous structures adjacent to the cilia (Fig. 4*b*). Although we have been unable to identify these bodies with certainty, they are reminiscent of the outer segments of photoreceptor cells; similar disk-like membranous structures have been found in human retinoblastoma cells[19].

Ad 12 HER1 cells are completely permissive for Ad 12 virus replication and we are attempting to isolate Ad 12 E1 mutants by complementation on this cell line. However, recombination between transfecting mutated viral genomes and the abundant Ad 12 sequences in this cell line, may preclude the isolation of E1 mutants. Therefore, we are also attempting to isolate mutants on other pAsc2-transformed HER and HEK lines which contain low copy numbers of integrated Ad 12 early region 1.

Whereas the use of liquid-phase saturation-hybridization with radiolabelled adenovirus DNA to screen DNA and RNA from a large number of human cancers failed to detect adenovirus-specific sequences[20–23], it has been claimed that adenovirus-related mRNA can be detected by *in situ* hybridization of radiolabelled adenovirus DNA onto cryostat sections of human neurogenic tumours[24]. Although many adenovirus serotypes cause eye infections, the only circumstantial evidence that Ad 12 may cause ocular diseases is derived from animal models of retinoblastoma[11,12]. The evidence presented here demonstrates that cloned Ad 12 E1 region can transform human cells, and as Ad 12-transformed human embryo retinoblasts produce tumours which resemble poorly differentiated retinoblastomas, we believe that further study of retinoblastomas for adenovirus nucleic acids is warranted.

We thank Professor D. G. Harnden for his encouragement throughout this study and for helpful discussion of the manuscript, Dr D. R. Barry for help with the tumour pathology, Val Nash and Paul Reeve for technical assistance, Sue Williams for printing the illustrations and Debbie Williams for typing the manuscript. This study was supported by the Cancer Research Campaign (CRC). P.H.G. is a CRC Fellow.

Circulating immune complexes in infants fed on cow's milk

**R. D'Amelio*, R. Seminara*, E. Galli†,
G. Antoniazzi†, L. Businco† & F. Aiuti***

* Department of Clinical Immunology and † Pediatric Clinic I,
University of Rome, 00161 Rome, Italy

Delire *et al.*[1] have reported antigen–antibody (Ag–Ab) complexes in newborns, fed on cow's milk, 6 days after birth, whereas they were absent from breast-fed neonates. The method they used was the inhibition of latex-IgG agglutination by polyclonal rheumatoid factor (pRF), linked to the Ag–Ab complexes[2]. The presence of immune complexes was attributed to the passage through the placenta of maternal IgG with antibody activity against proteins in cow's milk. This interpretation was also based on the characterization of the Ag–Ab nature of the immune complex-like material. We have now used the same and a different method to study a similar population of newborns. Our results are very different from those of Delire *et al.* We conclude that the possible pathogenicity of immune complexes cannot be assessed on the basis of a single insensitive test and in the absence of symptoms of serum sickness.

We have studied a population of newborns similar to that examined by Delire *et al.*, 24 bottle-fed and 53 breast-fed, for the presence of immune complexes in cord sera and serum samples collected 6 days after birth. We have used the same method as Delire *et al.*[1] and, in addition, the Clq–SP assay of Hay *et al.*[3].

Our results obtained with the pFR-inhibition test were very different from those of Delire *et al.*; in fact we observed a very high incidence of immune complexes in umbilical cord sera, and no significant change 6 days after birth. Furthermore, there was no difference between breast-fed and bottle-fed neonates and the increase in the number of immune complexes was absolutely random (Table 1).

Table 1 Immune complexes detected by pRF-inhibition method in neonates

Subjects	*N*	Cord blood	Day 6
Breast-fed	53	20 (38%)	19 (36%)
Bottle-fed	24	5 (21%)	4 (17%)

In contrast, using the Clq–SP assay we found only three samples of cord sera positive for immune complexes and, 6 days after birth, only two sera were positive, both in the breast-fed group (Table 2).

These observations stress the fact that the same serum populations can give very different results with different methods for immune complex evaluation. In the Clq–SP assay, using *Staphylococcus aureus* protein A as detector, it is mainly IgG1 complexes that are identified, whereas the pRF-inhibition test has a wider spectrum of detection.

Table 2 Immune complexes detected by Clq–SP method in neonates

Subjects	*N*	Cord blood	Day 6
Breast-fed	53	3 (6%)	2 (4%)
Bottle-fed	24	0	0

The difference between our data and those of Delire could be due to the fact that the pFR-inhibition test used, although simple and easy to perform, has too subjective a reading, depends on the source of pFR used (which may affect agglutinating activity) and on the IgG levels on the surface of the latex particles. Furthermore, it is very important that the presence of immune complexes be linked with symptoms of serum sickness.

Thus, we believe that it is impossible to draw conclusions about the pathogenic role of Ag–Ab complexes on the basis of a single insensitive test and in the absence of characteristic symptoms.

Binding of C3b proceeds by a transesterification reaction at the thiolester site

**Margaret K. Hostetter, Matthew L. Thomas,
Fred S. Rosen & Brian F. Tack†**

Department of Pediatrics, Harvard Medical School and the
Division of Immunology, Children's Hospital Medical Center,

The binding of C3b, the opsonic fragment of the third component of complement (C3), to bacterial surface structures mediates two events important in host defence: assembly of the $\overline{\mathrm{C5b\text{-}C9}}$ lytic complex and opsonic recognition by phagocytic cells (for reviews see refs 1, 2). These interactions proceed through a labile binding site[3] located on the α' chain of the C3b molecule, with the resultant formation of a covalent oxy-ester bond[4,5] in which the acyl group is contributed by the protein. By exposure of a titratable sulphydryl group[6,7] an internal thiolester of native C3 has also been localized to the α' chain. Studies with ^{14}C-methylamine, a nucleophile which is inherently reactive with a thiolester, have further indicated a stoichiometric (1:1) and covalent interaction, again within the α' chain[8–10]. After reaction of the native protein with ^{14}C-methylamine and radioalkylation of the exposed sulphydryl with ^{3}H-iodoacetic acid, a 35-residue tryptic peptide has been isolated that yields the sequence -Cys^{9}-Gly-Glu-Glu^{12}- on Edman degradation; tritium counts are released at step 9 (*S*[^{3}H]-(carboxymethyl)cysteine) and ^{14}C counts at step 12 (γ-glutamyl[^{14}C]methylamide)[8]. We now present data which directly demonstrate that the second glutamyl residue of the reactive thiolester can, on proteolytic cleavage of the protein, donate its carbonyl group in a transesterification reaction with appropriate acceptor molecules. These results provide a model for analysis of the interactions at the molecular level between surface constituents of microorganisms and C3b.

Small molecules such as oligosaccharides and amines have been shown to inhibit C3 uptake onto Sepharose–trypsin matrices[11,12], while other studies have shown direct incorporation of radiolabelled sugars and amino acids into nascent C3b and have localized the site of incorporation to the α' chain[13,14]. To define this site more precisely, purified human C3[15] was cleaved into fragments C3a and C3b in the fluid phase by limited tryptic digestion[16] in the presence of 100 mM ^{14}C-sucrose, ^{14}C-D-glucosamine or ^{14}C-glycerol (NEN; each diluted to a specific activity of 1.5 mCi mmol^{-1}). For all experiments, C3 was >80% native as assessed by sulphydryl group titration in the presence and absence of methylamine[8,16]. Controls for each reaction included native C3 without trypsin (C3) and pretrypsinized C3 (C3b), incubated in identical conditions of temperature

† Present address Department of Molecular Immunology, Research Institute of Scripps Clinic, La Jolla, California 92037, USA

Table 1 Incorporation (mol per mol) of radioactive ligand into total C3

	C3	C3b	C3 + trypsin
^{14}C-sucrose	0.42	0.45	0.72
^{14}C-glucosamine	0.19	0.13	0.20
^{14}C-glycerol	0.04	0.04	0.35
^{14}C-threonine	0.02	0.05	0.63

Incorporation was determined by measurements of radioactivity and absorbance at 280 nm ($E^{1\%}_{1\,\mathrm{cm}} = 9.3$)[24].

(37 °C) and time with each of the radiolabelled compounds. Results of SDS-polyacrylamide gel electrophoresis and autofluorography are presented in Fig. 1. For each sample, incorporation of ligand, expressed as mols of ligand per mol C3, is shown in Table 1. An identical study was performed with 100 mM ^{14}C-L-threonine (Amersham; uniformly labelled, diluted to a specific activity of 0.83 mCi mmol^{-1}), and the results are shown in Fig. 2 and Table 1.

These experiments demonstrate that generation of C3b (C3 + trypsin) in the presence of either ^{14}C-glycerol (Fig. 1) or ^{14}C-threonine (Fig. 2) results in covalent binding of the ligand specifically to the α′ chain. The negligible (≤0.05 mol per mol) incorporation of these two compounds into the control samples (C3, C3b) confirms that proteolytic cleavage of native C3 is a requirement for the covalent binding interaction and emphasizes the short lifetime of the labile binding site in C3b. In contrast, although ^{14}C-sucrose and ^{14}C-glucosamine are incorporated preferentially into the α′ chain (C3 + trypsin), a significant amount of label is associated with both chains of the control C3 and C3b samples (Fig. 1). These high levels of nonspecific incorporation for sucrose and glucosamine precluded their use in further studies (Table 1). By analogy, radiolabelled glucose preparations have frequently been shown to be contaminated with high specific activity components which react nonspecifically and covalently with proteins[17].

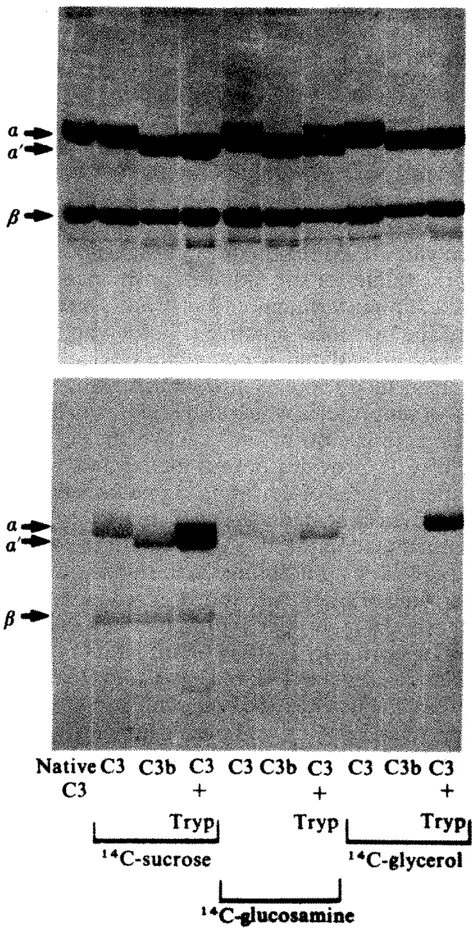

Fig. 1 SDS gel and autoradiogram of human C3 preparations reacted with ^{14}C-sucrose, ^{14}C-D-glucosamine and ^{14}C-glycerol. Each sugar derivative was reacted with the following C3 species: native (C3); pretrypsinized (C3b); trypsin-activated (C3 + trypsin). The far left lane represents untreated native C3. Purified C3 was dialysed overnight at 4 °C against 0.01 M Tris-HCl (*p*H 7.5), 0.15 M NaCl, 0.002 M Na$_2$EDTA. Trypsin digests (0.05%, w/w) were terminated at 16 min (37 °C) with the addition of a 10-fold molar excess of soybean trypsin inhibitor (Worthington). Samples were reduced in 1% SDS, 0.01 M dithiothreitol (2 h, 37 °C), alkylated with iodoacetamide (10% in excess of reducing thiol) and dialysed against 0.1 M Tris-HCl (*p*H 8.0), 0.01 M Na$_2$EDTA, 0.1% SDS. In the upper panel the chain structure of C3 (α, β) and C3b (α′, β) is visualized by staining the 7.5% polyacrylamide slab gel[25] with Coomassie blue R250. The lower panel shows the corresponding gel prepared for autofluorography[26].

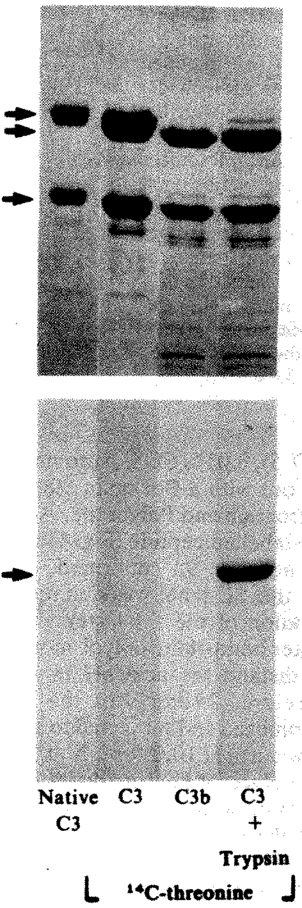

Fig. 2 SDS gel (upper panel) and autoradiogram (lower panel) of human C3 preparations reacted with ^{14}C-L-threonine. See Fig. 1 for description of method.

Accordingly, preparative experiments which would yield sufficient quantities of glycerol- or threonine-labelled protein for sequence analysis were performed. Purified human C3 (50 mg) was reacted with TPCK-trypsin in limited conditions in the presence of 100 mM ^{14}C-glycerol (0.25 mCi mmol^{-1}) or 100 mM ^{14}C-threonine (0.28 mCi mmol^{-1}). The mixture was treated with activated thiol–Sepharose and the bound C3b subjected to extensive trypsin digestion. Isolation of the tryptic peptide containing the labile binding site and radio-alkylation of the exposed sulphydryl group with ^{3}H-iodoacetic acid (54.6 mCi mmol^{-1}) were carried out as previously described[8]. On elution of the tryptic peptides from Sephadex G-75 (Superfine), ^{3}H and ^{14}C radioactivity (d.p.m.) coincided in a single peak (Fig. 3) which was subsequently subjected to Edman degradation. The mol fraction of C3 that incorporated ^{14}C-glycerol or ^{14}C-threonine was 0.35 and 0.38, respectively. For the threonine-labelled peptide, material in the excluded peak represented incompletely digested sample.

The threonine-bearing peptide was lyophilized, dissolved in 1.0 ml distilled water and dialysed against 0.001 M *N*-ethyl-

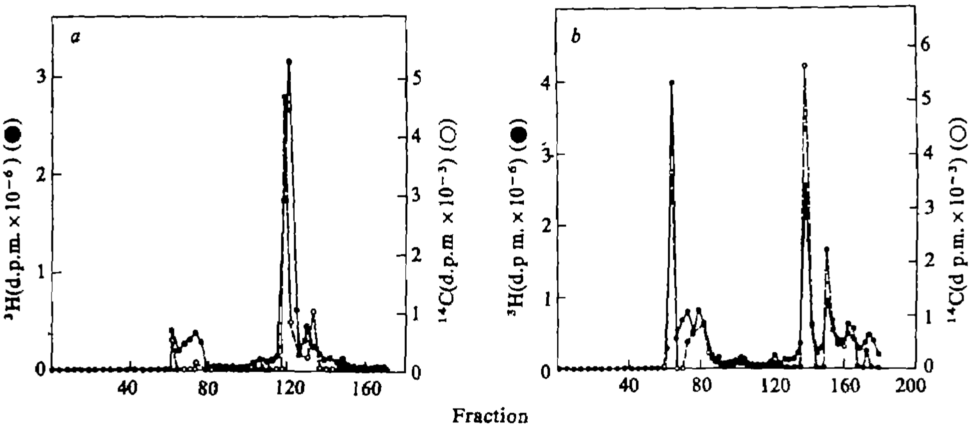

Fig. 3 Elution profile of the ^{14}C-glycerol-labelled (*a*) and ^{14}C-threonine-labelled (*b*) peptides. A 1.5×220 cm column of Sephadex G-75 SF was equilibrated with 0.01 M Tris-HCl (*p*H 8.0), 0.2% SDS, 0.001 M Na_2EDTA. Radioactivity coincided with the major peak of absorbance at 230 nm (not shown). The yield of glycerol-labelled peptide (35%) was calculated based on the known specific activity of ^{3}H-iodoacetic acid and nanomols of C3b bound to thiol-Sepharose. The yield of threonine-labelled peptide was 33%.

morpholine (*p*H 7.5), 0.01% SDS. Automated Edman degradation was carried out with a Beckman 890C sequencer using a 0.1 M Quadrol program and Polybrene. Analysis of 23.6 nmols of ^{14}C-threonine-labelled peptide (Fig. 4) showed the ^{3}H counts to be present at step 9, confirmed as *S*-[^{3}H]-(carboxymethyl)cysteine; the ^{14}C label was quantitatively recovered at step 12, the location of the thiolester glutamyl residue. The predicted oxy-ester bond of the polyol-modified peptide proved too labile to withstand the acid *p*H inherent in the Edman procedure. Therefore, 23 nmols of the ^{14}C-glycerol-bearing peptide were lyophilized and subjected to ammonolysis in 1.0 M ammonium acetate at *p*H 10.0 for 2 h at 37 °C. An additional 22.5 nmols of the glycerol-bearing peptide were left unreacted as a control, lyophilized and then dissolved in 1.0 ml distilled water. After dialysis against 0.001 M *N*-ethylmorpholine (*p*H 7.5), 0.01% SDS, the peptide treated with ammonium acetate released 66% of its ^{14}C counts, while all ^{14}C radioactivity remained bound in the control peptide. In neither peptide was release of ^{3}H counts detected. On Edman degradation of the amidated peptide, the ^{3}H label was recovered at step 9, identified as *S*-[^{3}H]-(carboxymethyl)cysteine, and >95% of the predicted glutamine was detected at step 12. For the experimental peptide, the recoveries of the phenylthiohydantoin derivatives were as follows for steps 9–13: (9) Cys, 2.3 nmols; (10) Gly, 1.6 nmols; (11) Glu, 1.1 nmols; (12) Glu, 0.7 nmols and Gln, 0.4 nmols; (13) Asn, 0.8 nmols. No glutamine was detected by HPLC at any of the first 14 steps in the non-amidated peptide.

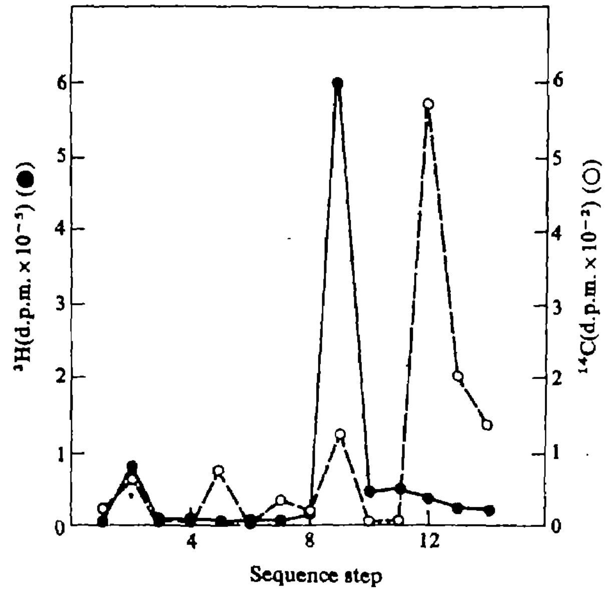

Fig. 4 Profile of the ^{3}H and ^{14}C counts observed on Edman degradation of the ^{14}C-threonine-labelled peptide. The recoveries of specific counts were 33% of the ^{3}H at step 9 and 16% of the ^{14}C at steps 12, 13 and 14.

The specific labelling data obtained in these studies clearly demonstrate that the second glutamyl residue, contained in the C3 sequence -Cys-Gly-Glu-Glu-, is the reactive species involved in covalent bonding with small molecules. In the native protein this residue participates in the formation of a thiolester bridge to the cysteinyl sulphydryl group. On proteolytic cleavage, this carbonyl group transesterifies with an acceptor molecule, releasing the cysteinyl sulphydryl. The reaction with glycerol is clearly one of *O*-acylation. For L-threonine, the resultant linkage with C3 is amide in nature (hydroxylamine insensitive[14], stable on Edman degradation). It is not possible, however, to distinguish between direct *N*-acylation of the α-amino group and/or *O*-acylation at the β-hydroxyl group with subsequent rearrangement through an *O–N* shift. *N*-acylation has been proposed to account for a stable linkage observed between C3b and the Fd region of rabbit IgG[18].

Recently, the thiolester site has been positioned by sequence analysis at the amino-terminal end of C3d[19], a subdomain of the α' chain. The presence in native C3 of a reactive thiolester is not, however, an isolated phenomenon: evidence has been presented for an identical site in α_2-macroglobulin[8,20] and in C4[21,22]—two other proteins which also function in host defence. Thus, the characterization of the reactive species involved in the binding of C3b provides both a model and a method for identifying specific sites of acylation on pathogenic organisms in which phagocytosis is mediated by C3b.

We thank Paul Gallop for his suggestion of the ammonolysis reaction and for discussion during these studies; we also thank Alex Law for suggesting the use of L-threonine. A preliminary report of these data has been presented elsewhere[23]. This research was supported by USPHS Grant AI 17146, American Heart Association grant 80-841 and by a Child Health Research Grant from the Charles H. Hood Foundation to M.K.H.; B.F.T. is the recipient of an Established Investigatorship (77-168) from the American Heart Association.

Translation of mRNA for human granulocyte–macrophage colony stimulating factor

Aldons J. Lusis*†, David W. Golde*, Diana H. Quon* & Laurence A. Lasky‡

Massachusetts 02115, USA

Granulocyte–macrophage colony stimulating factors (GM-CSFs) regulate the growth and differentiation of committed granulocyte and macrophage progenitor cells[1–3]. Operationally, the factors are recognized by their ability to stimulate the formation of granulocyte and macrophage colonies in semi-solid cultures of bone marrow cells. GM-CSFs are produced by a variety of tissues, and prominent cellular sources in man include T lymphocytes and mononuclear phagocytes[1,4–7]. The factors obtained from most sources are glycoproteins of molecular weight 20,000–70,000. At least two major GM-CSF subtypes have been distinguished in mice and humans on the basis of biological activity *in vitro*: one primarily stimulates the formation of macrophage colonies, while the other stimulates the fomation of both granulocyte and macrophage colonies[1,8]. We report here the translation and partial characterization of a messenger RNA for human GM-CSF that stimulates both granulocyte and macrophage colonies. The mRNA was isolated from a human T-lymphocyte cell line, and when injected into *Xenopus laevis* oocytes[9] it directed the synthesis of biologically active GM-CSF.

Human GM-CSFs have been partially purified and characterized from urine and from medium conditioned by placenta, leukocytes, lung and several tumour cell lines[1]. For our studies of GM-CSF mRNA we used a human cell line (Mo) containing predominantly helper T lymphocytes that constitutively produces and secretes into the medium a GM-CSF stimulating the formation of both granulocyte and macrophage colonies *in vitro*[10,11]. The Mo cell line is an exceptionally rich source of GM-CSF and unlike most other sources, appears to produce a single GM-CSF subtype. The production of GM-CSF is approximately doubled by the inclusion of phytohaemagglutinin in the culture medium[10]. Physically the Mo cell GM-CSF is an acidic glycoprotein of molecular weight ~30,000 (ref. 11).

Whole cell RNA was isolated from Mo cells using a guanidine thiocyanate extraction procedure[12], and poly (A)-containing RNA was enriched using oligo (dT)-cellulose chromatography[13]. The resultant poly(A) RNA was contaminated to ~50% with ribosomal RNA as judged by agarose gel electrophoresis and a tritiated poly(U) hybridization assay[14]. Oocytes were injected with 30–50 ng of the poly(A) RNA, and after 1–3 days' incubation the oocyte culture medium stimulated the formation of clusters and small colonies in agar cultures of human bone marrow. For example, when injected oocytes were incubated for 3 days in Barth's medium (20 µl medium per oocyte) containing 0.1% bovine serum albumin, 200 µl of the medium stimulated the formation of an average of ~40 small colonies containing 15 or more cells in the standard GM-CSF assay. The assay involves monitoring the formation of granulocyte and macrophage colonies in 1-ml cultures containing 10^5 light-density human bone marrow cells plated in 0.3% agar, α-medium and 10% fetal bovine serum[2,15,16]. In contrast, the medium from oocytes injected with water or poly(A)-containing RNA from rat liver did not stimulate colony formation.

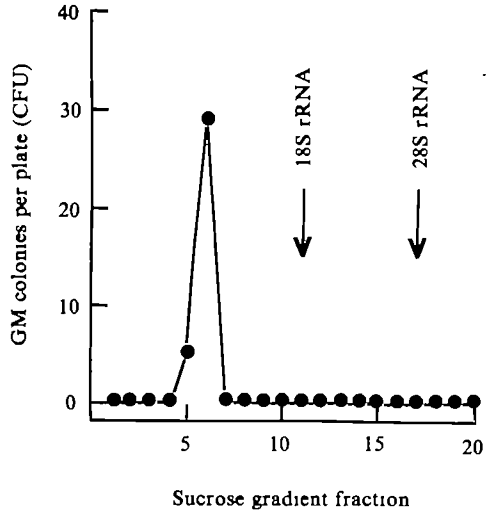

Fig. 1 Fractionation of Mo T-cell poly(A)-containing RNA using sucrose gradient centrifugation. Mo cells were grown and induced for 48 h with phytohaemagglutinin (Burroughs-Wellcome) as described previously[21] In these conditions GM-CSF production increased approximately two-fold over that of uninduced cells[10]. Total RNA was isolated by a procedure involving guanidine thiocyanate extraction followed by centrifugation through a caesium chloride cushion[12]. The poly(A) RNA was then isolated by chromatography on oligo(dT)-cellulose (Collaborative Research) Judging from electrophoretic analysis and a tritiated poly(U) hybridization assay, ~50% of the RNA at this stage was ribosomal[14]. The yield of total RNA from 10^9 cells averaged 3–4 mg, and of this ~3% was recovered following oligo(dT)-cellulose chromatography The RNA had a 260 nm/280 nm absorbance ratio of 2.1 or better, indicating low protein contamination. The poly(A) RNA was heated at 65 °C for 1 min and 100 µg was applied to a 10-ml 5–25% sucrose gradient containing 0.1 M sodium chloride, 10 mM Tris *p*H 7.4, and 1 mM EDTA. The gradient was centrifuged in a Beckman SW 41 rotor at 26,000 r.p.m. for 19 h at 4 °C and 0.5-ml fractions were collected and precipitated with two volumes of ethanol. The RNA precipitates were dissolved in 5 µl of water. An aliquot of the RNA was removed for analysis by electrophoresis on 1% agarose gels, the results indicated good separation of RNA on the basis of size, with 18S and 28S ribosomal RNA being present mainly in fractions 11 and 17. RNA from each fraction was injected into 20 oocytes (50 nl per oocyte) and the pooled oocytes from each fraction were incubated at room temperature in 200 µl of modified Barth's medium containing 1% bovine serum albumin (Sigma, crystallized) for 2 days. The medium from each fraction was then assayed for GM-CSF using cultures of human bone marrow as described in Fig. 2 legend Fraction 6, containing the bulk of the GM-CSF mRNA activity, contained ~4 µg of RNA. The arrows indicate the positions of 18S and 28S ribosomal RNA markers present in a gradient run in parallel CFU, colony-forming units.

For these experiments it was important to use non-adherent bone marrow cells in the assay because in some cases the presence of adherent cells in the cultures produced a background of clusters that made it difficult to detect the small amount of activity present in oocyte medium[15]. Also, the presence of protein (0.1% bovine serum albumin) in the oocyte medium appeared to stabilize the activity stimulating colony formation. Homogenates of oocytes injected with Mo poly(A) mRNA stimulated few colonies; this phenomenon may be attributed in part to an inhibitor of colony formation present in the oocytes (see below). The numbers of colonies produced in different experiments varied considerably, probably due to donor-specific differences in bone marrow and variability in frog oocytes. This variability made it difficult to ascertain whether treatment of the Mo cells with phytohaemagglutinin stimulated GM-CSF mRNA activity; nevertheless, for experi-

0028–0836/82/260075—03$01 00

ments described below, RNA was extracted from Mo cells treated with the lectin.

A control experiment in which mRNA preparations were added directly to bone marrow cultures indicated that contaminating GM-CSF in the RNA was not responsible for the stimulation of colony formation. The addition of 500 ng of sucrose gradient-purified GM-CSF mRNA (see below) to duplicate cultures of bone marrow cells did not result in the stimulation of colony formation, while medium derived from 10 oocytes injected with a comparable amount of the same mRNA stimulated the formation of up to 30 granulocyte–macrophage colonies containing ≥20 cells.

The CSF signal obtained when total poly(A) RNA was injected into oocytes was usually low, with few colonies containing relatively small numbers of cells. The poly(A) RNA was therefore fractionated according to size using sucrose gradient centrifugation, and the resultant fractions injected into oocytes. RNA in each fraction from the gradient was precipitated with ethanol and resuspended in 5 μl of H_2O. Agarose gel electrophoresis and *in vitro* translation using reticulocyte lysates[17] demonstrated the presence of translatable poly(A) mRNA in each fraction. An aliquot (50 nl) of each fraction was injected into each of 20 oocytes, and the oocytes from each fraction were incubated together in 20 μl of medium for 2 days. Assay of the medium in human bone marrow cultures indicated that the CSF activity was present in a single sharp peak of RNA from the sucrose gradient (Fig. 1). Using 18S and 28S ribosomal RNA markers, the size of the GM-CSF mRNA was estimated at about 1,200 nucleotides. A mRNA of this size could be translated into a protein having a maximum molecular weight of 44,000—this compares with a molecular weight of ~30,000 for GM-CSF produced by the Mo cells as estimated by gel filtration chromatography[11] or SDS-polyacrylamide gel electrophoresis (A.J.L., unpublished). As the Mo GM-CSF is glycosylated, the information content in the mRNA is more that sufficient to encode this protein. The sucrose gradient fractionation was performed three separate times with identical results.

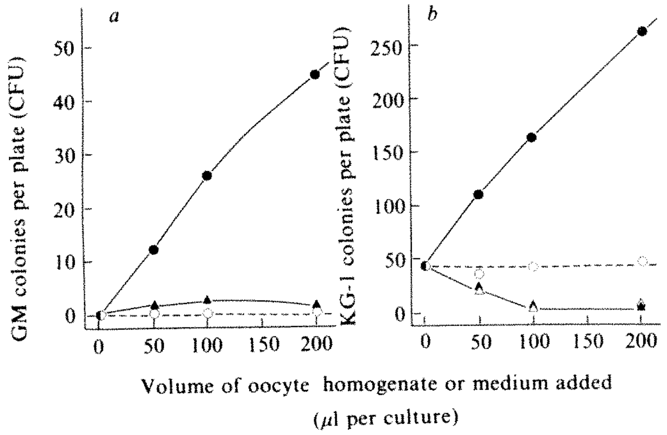

Fig. 2 Clonal assay of GM-CSF translated by oocytes using human bone marrow (*a*) and the KG-1 human myeloid leukaemia cell line (*b*). Oocytes were injected with 40 ng of RNA purified from the Mo T-cell line using oligo(dT)-cellulose chromatography and sucrose gradient centrifugation as described in Fig. 1 legend. The oocytes were incubated, in pools of 10, in 200 μl of modified Barth's medium containing 1% bovine serum albumin for 2 days at room temperature. The oocyte incubation medium was removed and the oocytes were homogenized in 0.02 M sodium phosphate, 0.15 M NaCl, *p*H 7.4 (20 μl per oocyte). The debris was removed by centrifugation at 12,000*g* for 10 min. The oocyte homogenates and media were then assayed in clonal assays using human bone marrow target cells as previously described[11,15,16]. Briefly, bone marrow cells were aspirated from healthy adult volunteers, and the light-density, non-adherent cells were isolated using sedimentation in Ficoll–Hypaque followed by Petri dish adherence. 10^5 fractionated cells were plated with varying amounts of oocyte homogenates or media in 1-ml cultures containing 0.3% agar, 10% fetal bovine serum, α-medium (Flow) and α-thioglycerol. The cultures were then incubated for 11 days at 37 °C in 7% carbon dioxide, when they were examined using a low power microscope and colonies of ≥30 cells counted. In tests on the KG-1 human myeloid leukaemia cell line, the cells were plated in agar and cultured at a density of 2×10^3 cells m^{-1} culture exactly as described for bone marrow cells. Colonies containing ≥20 cells were counted after 11 days. Each point represents the average of two determinations. Medium from oocytes injected with mRNA (●) or water (○); homogenates of oocytes injected with mRNA (▲) or water (△).

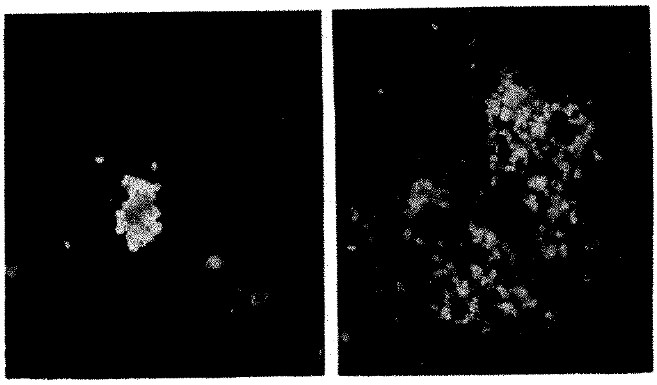

Fig. 3 Gross morphology of typical granulocyte–macrophage colonies stimulated by GM-CSF translated in frog oocytes. Both 'tight' (left) and 'loose' (right) colonies were also observed at low concentration of Mo T-cell conditioned medium (not shown). ×30

The enrichment of mRNA for GM-CSF by sucrose gradient fractionation resulted in a considerably stronger stimulation of colony formation by oocyte medium than was obtained using total poly(A)-containing RNA. In contrast to the relatively small colonies observed using unfractionated RNA, peak gradient fractions, when injected in quantities of 25–50 ng per oocyte, stimulated relatively large colonies containing up to ~300 cells. For example, in the experiment shown in Fig. 2, 200 μl of oocyte medium derived from 10 oocytes injected with fractionated mRNA and incubated for 2 days, stimulated more than 40 colonies containing ≥30 cells as well as numerous smaller clusters. In terms of colony number, size and morphology, the GM-CSF in 200 μl oocyte medium resulted in stimulation equivalent to ~4 μl of medium conditioned by the growth of Mo cells for 3 days at a final density of 5×10^6 cells ml^{-1} (Fig. 3). Because of its higher specific activity, sucrose gradient fractionated preparations of GM-CSF mRNA were used in the experiments described below.

The GM-CSF produced by frog oocytes stimulated colony formation dose dependently (Fig. 2). The curve resembles that found previously for the GM-CSF produced by Mo T cells[10,11]. Also, the activity in oocyte medium produced colonies that were similar morphologically to those observed using low levels of T-cell conditioned medium (Fig. 3). Microscopic examination of individual cells from the colonies indicated the presence of monocytic, granulocytic and mixed monocytic–granulocytic colonies (data not shown). For these experiments, single colonies were picked from agar cultures using a fine pipette, dissociated from the agar by a stream of air and stained with Wright's or Giemsa. Monocytic colonies were identified using a lipase stain specific for monocytes and macrophages[11]. Using this procedure, 50–100 μl of medium from injected oocytes stimulated an average of 56% monocytic colonies, 37% granulocytic colonies and 7% mixed colonies. A comparable concentration of T-cell-derived GM-CSF gave similar results, with 49% of the colonies being monocytic, 42% granulocytic and 9% mixed.

The bulk of the GM-CSF activity produced by the oocytes was apparently secreted into the medium (Fig. 2). However, the determination of GM-CSF activity in oocyte homogenates is complicated by the presence of a weak inhibitor of colony formation. For example, in mixing experiments, 200 μl of control oocyte homogenate from the experiment shown in Fig. 2 produced ~40% inhibition of the activity of added Mo T-cell GM-CSF. Taking this inhibition into account, ~90% of the GM-CSF produced by oocytes is present in the medium after 2 days. Because of the relatively small amount of activity produced by injected oocytes, a detailed physical characterization of the oocyte-derived GM-CSF has not been possible. However, preliminary experiments have shown that the activity produced by oocytes had a heat inactivation profile similar to that of the GM-CSF produced by Mo T cells. When incubated at neutral *p*H for 30 min both activities were stable at 60 °C but were almost completely inactivated at 80 °C.

The GM-CSF translated in oocytes also stimulated the growth in agar of a human myeloid leukaemia cell line, KG-1, that has previously been shown to be specifically responsive to GM-CSF[18,19] (Fig. 2). As in the case of bone marrow cells, medium from oocytes injected with water or control RNA had no effect on the growth of KG-1 cells. However, homogenates of both injected and uninjected oocytes significantly inhibited cell growth (Fig. 2).

The GM-CSF mRNA assay will undoubtedly be useful for the isolation of cloned cDNAs which contain GM-CSF nucleotide sequences. Similar oocyte translation systems have proved useful for studies of interferons[20]. Clearly, molecular genetic approaches should aid the examination of the structural and functional properties of these mediators of haematopoiesis. Our results also suggest that it should be feasible to use the oocyte system for the translation and characterization of mRNAs for other factors regulating the growth and differentiation of haematopoietic cells.

A common mechanism for the synthesis of membrane and secreted immunoglobulin α, γ and μ chains

W. Cushley*, B. E. H. Coupar, C. A. Mickelson* & A. R. Williamson†

Department of Biochemistry, University of Glasgow,
Glasgow G12 8QQ, UK

Immunoglobulins serve as both secreted effector antibodies and antigen receptors bound to the membrane of lymphocytes. Each newly generated B lymphocyte expresses membrane IgM and subsequently co-expresses membrane IgM and membrane IgD. Antigen-driven clonal proliferation is accompanied by further differentiation with the generation of B lymphocytes expressing, in membrane-bound form, other classes and subclasses of immunoglobulin[1]. Such memory cells are apparently capable of responding to antigen to generate further clones of cells secreting antibodies of particular classes and subclasses. The mechanism by which IgM functions as both a membrane-bound and a secreted immunoglobulin has been determined for both murine and human systems[2–4]. The difference between the two forms of IgM is entirely at the C-terminus. The μ_s (secreted) chain has a hydrophilic peptide additional to the Cμ4 domain and the μ_m (membrane-bound) chain has a hydrophobic peptide replacing the hydrophilic C-terminal peptide of the μ_s chain[2–4]. The μ_s and μ_m chains are translated from distinct mRNA molecules that are generated by alternative splicing and/or termination points of transcripts from a single rearranged μ gene[5,6]. Recent evidence supports the existence of a similar mechanism for the generation of δ_s and δ_m chains[7–9]. Structurally different γ_m and γ_s chains have been observed in human, mouse and chicken cells[10–12].The present study further distinguishes between γ_m and γ_s chains and characterizes the mRNA molecules encoding them in human cells. We have also characterized α_m and α_s chains in a human cell. The data reported here, together with other recent findings, suggest a common mechanism for the generation of membrane and secreted forms of α, γ and μ chains.

We have compared the biosynthesis of IgG in three different human B-cell lines (EB4, Bec-11 and Maja) with that of IgA in the human cell line Dakiki Arosros I and of IgM in the human line Bjab. The membrane and secretory heavy chains of Bec-11, Dakiki and Bjab immunoglobulins have been fully characterized previously[10,13]. Two forms of biosynthetically labelled, specifically immunoprecipitable γ chains of EB4 cells are clearly resolved by SDS-gel electrophoresis (Fig. 1), differing in apparent molecular weight by 12,000 whether glycosylated or not. The high molecular weight band can be identified as γ_m by iodination of intact cells (Fig. 1*e*), and the lower molecular weight γ chain as γ_s by demonstrating its secretion in either the glycosylated (Fig. 1*h*) or non-glycosylated (lane *i*) state. The cell line Maja synthesizes two γ polypeptide chains similar in size to the γ_m and γ_s chains of Bec-11 and EB4 cells. M. J. Owen (personal communication) has characterized the γ_m and γ_s chains of Maja cells. The three cell lines show three different patterns for glycosylation of γ chains: in EB4, both γ_m and γ_s seem to be singly glycosylated; in Bec-11 some γ_s chains have a second oligosaccharide unit added but γ_m chains are singly glycosylated; and in Maja cells a substantial proportion of both γ_m and γ_s chains have a second oligosaccharide unit added to the polypeptide chain.

When non-glycosylated, the γ chains of the three cell lines have different electrophoretic mobilities but in each line the apparent molecular weights of the γ_m and γ_s forms differ by ~12,000. This is in contrast to the difference in apparent

Table 1 C-terminal amino acid sequences of human immunoglobulin heavy chains

Protein*	H chain class	Residue no.	Sequence
Ou (16)	μ	609	G K P T L Y N V S L V M S D T A G T C Y
Bur (17)	α	477	G K P T H V N V S V V M A G V D G T C Y
Zuc (18)	γ	477	G (K)
ND (19)	ε	609	G K

The C-terminal amino acid sequences of human μ, α, γ and ε chains from the glycine residue located at the end of the last constant region domain to the end of the polypeptide are shown. The myeloma proteins given are representative of the equivalent sequences found in other myelomas. The C-terminal lysine of the γ-chain is shown in parentheses as it is not always found in the polypeptide although it is ubiquitous in the gene sequence[15].

molecular weight between μ_m and μ_s (~3,000) and α_m and α_s (~2,000). Comparison of the C-terminal amino acid sequences of α_s, γ_s and μ_s chains reveals a conserved Gly-Lys sequence at the end of the terminal domain followed, in the case of α and μ chains, by highly homologous hydrophilic tail sequences (Table 1). Neither ε nor γ_s chains possess this tail sequence (Table 1). In the murine μ gene, the Gly-Lys sequence encodes a consensus splice site used in the generation of μ_m mRNA[3]. It is therefore proposed that this splice site is conserved in α and μ genes. The similarity between the hydrophilic tail sequences of α and μ genes would be consistent with a common evolutionary origin for the membrane exons for these two classes and this would explain the similar size difference between the membrane and secreted forms of the chains. In this model, the hydrophilic tailpiece of γ_s is a single lysine residue. We propose that the hydrophobic, immunoglobulin domain-sized tailpiece on γ_m chains had a separate evolutionary origin from the *M* exons of α and μ chains.

To test the hypothesis that the γ_m and γ_s polypeptides are translated from different mRNA molecules, the specific mRNAs coding for γ chains in cell lines EB4 and Bec-11 were identified. Total poly(A)-containing RNA was prepared from each cell line, resolved electrophoretically in denaturing conditions, transferred to diazobenzyloxymethyl paper and hybridized to a genomic γ2 DNA probe. This probe detects 3.3 and 1.4 kilobase (kb) γ mRNA in EB4 RNA (Fig. 2). The higher molecular weight mRNA is of lower intensity than the lower molecular weight RNA. This difference is consistent with our interpretation that the 3.3 kb mRNA encodes γ_m and the 1.4 kb species γ_s. In the highly stringent conditions used to obtain the data shown in Fig. 2, the γ2 probe only detects the 1.4 kb component in Bec-11 mRNA. In less stringent conditions, the γ2 probe gives a more intense hybridization signal in the 1.4 kb position and shows some hybridization to the 3.3 kb component (data not shown). The difference between the results obtained with EB4 and Bec-11 is consistent with the much lower ratio of γ_m to γ_s polypeptides in Bec-11 cells than in EB4 cells (Fig. 1) and might be related to a subclass difference between EB4 and Bec-11 γ chains.

To account for the molecular weight difference between γ_s and γ_m polypeptide chains the γ_m message would need to be only 0.3 kb larger than the γ_s mRNA. The observed size difference of 1.9 kb is in close agreement with the reported difference of 2 kb between murine γ^2a_s and γ^2a_m mRNAs[14]. The most likely explanation for the unexpected size difference between γ_m and γ_s mRNAs is the presence of an extended 3'-untranslated region in the γ_m message (we have found no evidence for any other coding region in the 3.3 kb mRNA as we can detect no γ chains larger than γ_m). For comparison, μ_m and μ_s mRNA molecules are 2.7 and 2.4 kb respectively. The predicted coding difference would account for 63 base pairs (bp) and gene sequencing shows that the 3'-untranslated region of μ_m is 142 bp longer than that of μ_s mRNA[3]. The close agreement between the human and murine γ chain data are consistent with an early evolutionary divergence or separate origin for the *M* exons of γ and μ chains.

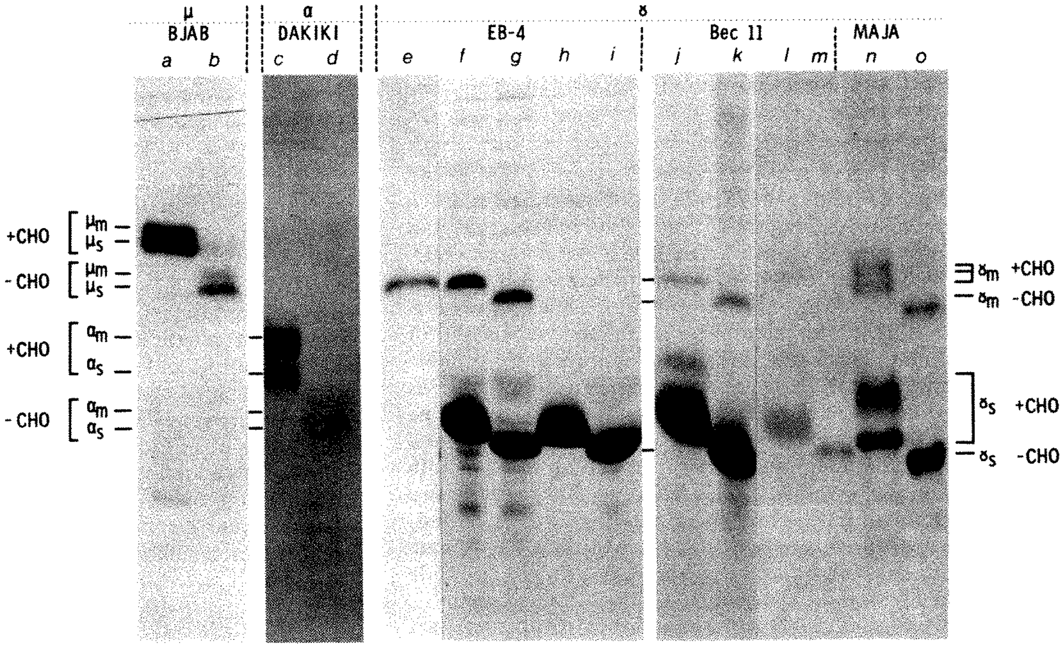

Fig. 1 Biosynthetic characterization of membrane and secretory forms of α, γ and μ polypeptide chains. The following human B-lymphoid cell lines were used: Bjab (IgM κ), Dakiki Arosros I (IgA λ), EB4 (IgG κ), Bec-11 (IgG κ), and Maja (IgG κ). An aliquot (2.5×10^6 cells) from log-phase cultures of each cell line was incubated in the presence or absence of tunicamycin (2 μg ml^{-1}) for 3 h at 37 °C in RPM1-1640 medium plus 10% (v/v) fetal calf serum (FCS). After preincubation, the cells were washed once in serum-free RPM1-1640 lacking methionine and then resuspended in 0.2 ml of the same medium containing 200 μCi ^{35}S-methionine and incubated at 38 °C for 90 min to effect metabolic labelling of cellular proteins. For pulse-chase experiments (lanes *h*, *i*), 50% of the culture was pelleted, resuspended in 0.5 ml of RPM1-1640 medium containing 10% (v/v) FCS and incubated at 37 °C for 4–6 h: the cells were pelleted and the supernate used for analysis of secreted proteins. Membrane proteins were radiolabelled by lactoperoxidase-catalysed iodoination. 10^7 cells were incubated for 3–4 min at 30°C in 70 μl of PBS-1 (50 mM sodium phosphate buffer *p*H 7.2; 150 mM NaCl) containing 10 μg lactoperoxidase and 1.25 mM H_2O_2: the reaction was terminated by addition of ice-cold 5 mM KI in PBS-I (1 ml). The cells were washed extensively before preparation of cell lysates. Cell lysates were prepared as follows[20]. Radiolabelled cells were washed once in ice-cold TKM buffer (0.1 M Tris-HCl *p*H 8.2, 0.1 M KCl and 5 mM $MgCl_2$) and resuspended in 235 μl of ice-cold 1% (w/v) Triton X-100 in TKM; the suspensions were placed on ice for 20–30 min to complete lysis. Nuclei were removed by centrifugation (5,000 *g* for 30 min) and deoxycholate and SDS were added to the supernatant to final concentrations of 1% (w/v) and 0.5% (w/v) respectively to yield lysates in 3D-TKM (1%(w/v) Triton X-100, 1% (w/v) deoxycholate and 0.5% (w/v) SDS in TKM buffer). Radiolabelled immunoglobulin was isolated by specific immunoprecipitation using 1 μl of rabbit antiserum to the appropriate light chain followed by addition of serological equivalence of goat anti-rabbit immunoglobulin antiserum. After overnight incubation at 4 °C, the immunoprecipitates were collected by centrifugation and washed by pelleting through a two-step discontinuous sucrose gradient in 3D-TKM. Aliquots of washed immunoprecipitates were dissolved in 25 μl of SDS polyacrylamide gel electrophoresis loading buffer [0.065 M Tris-HCl *p*H 6.8, 0.1% (w/v) SDS, 0.1 M dithiothreitol, 10% (w/v) glycerol and 0.001% (w/v) Bromophenol blue] and heated at 100 °C for 2 min. Reduced samples were electrophoresed on 10% (w/v) acrylamide slab gels using the discontinuous buffering system of Laemlli[21] [IgM samples derived from Bjab cells were analysed on a 12.5% (w/v) acrylamide slab gel]. Radioactive components were visualized by fluorography[22]. Lanes *a*, *b*, glycosylated and non-glycosylated μ chains respectively; *c*, *d*, equivalent samples derived from the α-chain-producing line Dakiki Arosros I. Radioiodinated membrane γ-chain of EB4 cells is shown in lane *e* and is compared with glycosylated and non-glycosylated γ-chains for EB-4 lysates (*f*, *g*) and supernatants (*h*, *i*); *j*, *k*, respectively glycosylated and non-glycosylated γ chains from Bec-11 cell lysates; *l*, *m*, similar results for Bec-11 cells (obtained in an independent experiment) compared with glycosylated (*n*) and non-glycosylated (*o*) γ chains of the cell line Maja to illustrate the ubiquity of the large size difference between γ_m and γ_s polypeptides.

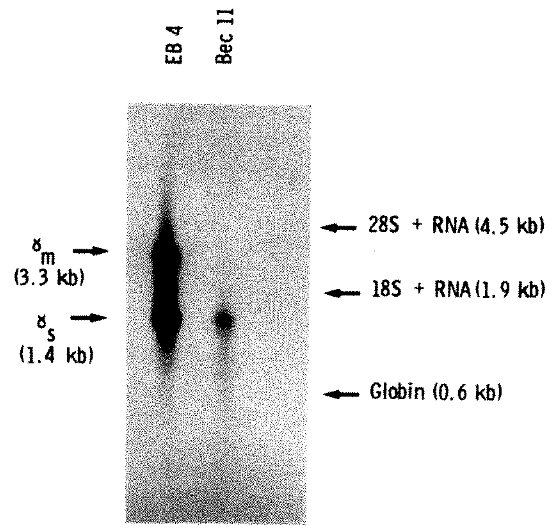

Fig. 2 Polyribosomes were prepared from 5×10^9 EB4 cells as previously described[20]. Poly(A)-containing RNA was extracted from polyribosomes by oligo(dT)-cellulose chromatography. Five μg of EB4 poly(A)-containing RNA was electrophoresed on a 1% (w/v) agarose gel containing 7.5 mM methyl mercury hydroxide. After electrophoresis, the separated RNA species were transferred to diazobenzyloxymethyl paper[23]. A DNA plasmid containing $\gamma2$ coding sequences of human genomic DNA was nick-translated to a specific activity of 1×10^8 d.p.m. μg^{-1} with [α-^{32}P]dATP and used as a probe for γ mRNA species contained in the EB4 poly(A)-containing RNA. Hybridization was done at 42 °C for 5 h in 50% formamide, $5\times$SSC, 0.1% bovine serum albumin, 0.1% polyvinylpyrrolidone, 0.1% Ficoll (molecular weight 400,000) 20 mM sodium phosphate *p*H 6.5, 10% sodium dextran sulphate 500 and 100 $\mu g\ ml^{-1}$ denatured sonicated salmon sperm DNA. Unhybridized label was removed by extensive washing in $0.3\times$SSC/0.1% SDS and hybridization visualized by autoradiography using an intensifier screen at −70 °C.

In cloned murine genomic DNA, two homologous regions, 270 and 250 bp long, are conserved at a position 1–2 kb 3′ to each of the γ subclass genes[15]. These regions are known to hybridize to the γ_m mRNA[14,15]. They are quite sufficient to encode the additional domain-size segment of γ_m chains but would not account for the size of the γ_m mRNA. The implication that the additional γ_m mRNA sequences are not conserved between γ subclasses further supports the argument that these additional sequences are non-coding.

We thank Irene Gall for assistance, George Klein for the Dakiki cell line, Mike Owen for the Maja cell line and Terry Rabbitts for the human $\gamma2$ DNA probe.

Deutsches Krebsforschungszentrum, Im Neuenheimer Feld 280,
D-6900 Heidelberg, FRG

Colony-stimulating factors (CSF) are glycoproteins essential for the formation of colonies of mature haematopoietic cells by single immature progenitor cells (colony-forming cells (CFC)). The number of colonies in semi-solid agar cultures can be used to determine the CSF concentration in biological fluids[1]. Various murine cells[2–6] are able to produce CSF *in vitro*. Supernatants of spleen cell cultures consisting of a mixture of T cells, B cells and macrophages are found to contain neutrophil-granulocyte–macrophage CSF (GM-CSF), CSF for megakaryocytes (Meg-CSF), eosinophilic granulocytes (Eo-CSF) and erythroid cells (E-CSF)[5]. The producer cells of these different CSF types, however, have not been defined[7]. We therefore determined here whether normal T cells produce CSF *in vitro* and whether GM-CSF, Meg-CSF, Eo-CSF and E-CSF are produced by different T-cell subsets or the progeny of single T-cell clones. Our results indicate that T cells at a high frequency (one out of three) produce CSF at variable amounts even in the absence of accessory cells following mitogen stimulation.

After stimulation of C57BL/6 (B6) spleen cells in bulk cultures with 5 $\mu g\ ml^{-1}$ concanavalin A (Con A) for 48 h, light density blasts were separated by centrifugation over Ficoll (1.077 $g\ cm^{-3}$). These cells (>95% Thy-1.2 positive) were subsequently grown in microcultures in limiting dilution conditions in the presence of allogeneic (AKR/J) irradiated (3300 r; ^{60}Co) peritoneal exudate filler cells (PEC) (10^4 per well) and 10% T-cell growth factor (TCGF) containing conditioned medium from 24 h Con A-stimulated rat (Sprague–Dawley) spleen cells (rat spleen cell conditioned medium (RSCM)). The T cells have a doubling time of ~15 h and clones derived from single or a few precursor cells grow to a clone size large enough to be tested in functional assays[8–12]. Following a growth period of 10 days during which the cells were fed twice with fresh RSCM, the cells were washed twice to remove CSF contained in RSCM and resuspended in fresh culture medium containing 10 $\mu g\ ml^{-1}$ Con A. After overnight incubation supernatants of all culture wells were assayed individually for CSF at a final concentration of 15% in 1 ml semi-solid agar cultures containing 7.5×10^4 CBA bone marrow cells. Seven days later the bone marrow cultures were scored for colony growth and the cellular composition of the colonies determined[13].

Table 1 % CSF-negative cultures of T cells plated in the presence of different numbers of filler cells

No. of PEC per well	T cells plated 1 per well	10 per well	20 per well
5×10^2	100	100	63
10^3	100	88	75
10^4	100	19	13
10^5	81	75	69

Limiting dilution analysis of B6 splenic T cells was performed as described in Fig. 1 legend.

Table 2 Con A-induced CSF production by TCGF-dependent cells

Long-term cultured cells	Growth dependent on		Production of CSF				
			Total no. of colonies (±s.e.)	Colonies (%)			
	Antigen	TCGF		GM	Meg	Eo	E
PC-AKR-clone 29	−	+	78±9	97	3	0	0
AKR-anti-B6 line PK 7.1.1b	+	+	126±15	86	2	6	6
AKR-anti-B6 line PK 7.1.2	+	+	113±11	90	4	1	5

The establishment of PC AKR clone 29 in long-term culture from antigen (picryl chloride)-stimulated AKR/J T cells has been described previously[18,19], as has the establishment of the alloreactive AKR anti-B6 T-cell lines PK 7.1.1b and PK 7.1.2[9,20,21]. Antigen used was irradiated allogeneic B6 stimulator cells. The number of colonies (controls) with a standard CSF: 127±24, NaCl: 0±0.

A representative experiment (Fig. 1) shows that, analysed according to the Poisson distribution (least square fit as well as the method of Porter and Berry[14]), the growth frequency of Con A-activated T cells initially plated in limiting dilution was approximately one out of two to three cells ($f = 1/2.2$ (least square method), $f = 1/2.5$ ref. 14, 95% confidence limit $f = 1/2.1$ to $f = 1/2.9$ (ref. 14)). The frequency of CSF producer cells was close to $f = 1/6$ (Fig. 1). Lower frequencies found in other experiments (Table 1) were essentially due to lower plating efficiencies. The plot of our data (Fig. 1) gave a straight linear regression line ($\chi^2 \sim 1$ for fit[14]) with an intercept at the ordinate at or close to 1.0. This suggests single-hit kinetics, indicating that the only limiting component for CSF production was the number of T cells initially seeded in microculture. This is supported by our observation that no CSF production occurred in cultures devoid of proliferating T cells (data not shown). Moreover, CSF production was not constitutive but absolutely dependent on Con A stimulation (data not shown).

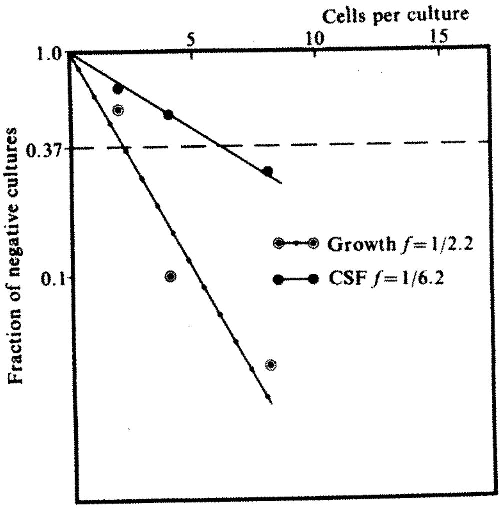

Fig. 1 Frequency of growing and CSF-producing Con A-activated splenic B6 T cells in limiting dilution. Two days after polyclonal activation by Con A and separation of the light density T-cell blasts over Ficoll, 2, 4 and 8 B6 cells were plated in microcultures (96 wells per group) and expanded on irradiated (3300 r) AKR/J PEC (10^4 per well) for 10 days in the presence of medium containing 10% RSCM from 24 h Con A-stimulated rat (Sprague–Dawley) spleen cells. After a growth period of 10 days the cells were washed twice to remove CSF contained in RSCM and resuspended in fresh culture medium containing 10 μg ml^{-1} Con A. After overnight incubation supernatants of all culture wells were assayed individually for CSF at a final concentration of 15% in 1 ml semi-solid agar cultures containing 75.000 CBA bone marrow cells. After 7 days the bone marrow cultures were scored for colony growth[13]. Cell growth in limiting dilution microwells was determined by microscopic inspection. Data were plotted according to Poisson's distribution and linear regression lines fitted to the least squares method. Frequencies were read from the number of responding cells corresponding to 37% negative cultures[8–12].

Note that the above procedure might favour selection of certain T-cell subpopulations. Con A activation (20–50% growth of Con A-activated murine spleen cells in bulk culture (data not shown)), Ficoll purification, growth in limiting dilution microcultures (growth frequency as high as $f = 1/2$) and induction of lymphokine release by Con A may have a selective effect. Nevertheless, we believe that this experimental system probably provides the most random evaluation available of the repertoire of functional T cells in non-immune mice[12].

Figure 2*a* shows the results of an analysis of CSF activity of supernatants from microcultures derived from the progeny of single or a few T-cell precursors. The quantity of CSF in such supernatants varied remarkably, and occasionally very high activities from low numbers of T cells could be observed. All active supernatants contained GM-CSF. Moreover, many supernatants with intermediate to high GM-CSF levels contained other types of CSF, for example, Meg-CSF, Eo-CSF and E-CSF. As the incidence of CFC for megakaryocytes, eosinophils and erythroid cells in the bone marrow is low, the semi-solid agar culture system only detects high concentrations of Meg-CSF, Eo-CSF and E-CSF. Therefore, some supernatants with only low GM-CSF levels may not be entirely negative for the other CSF types.

Table 3 Specificity of induction of proliferation and CSF release

Stimulator cells	*H-2* regions *K*	*A*	*J*	*E*	*C*	*S*	*G*	*D*	^{3}H-thymidine incorporation (±s.e.)	No. of colonies (±s.e.)
AKR	*k*	*k*	*k*	*k*	*k*	*k*	*k*	*k*	597±389	0
B6	*b*	*b*	*b*	*b*	*b*	*b*	*b*	*b*	25,089±3,545	18±5

10^4 Responder cells of the AKR anti-B6 T-cell line PK7.1.2 were used per well (triplicates, round-bottom microtitre plates, Greiner, Nürtingen, 96K). Irradiated (3300r) stimulator cells at a concentration of 10^5 per well were used after lysis of red blood cells. ^{3}H-thymidine incorporation (2.5 μCi per well) was determined after a 6-h pulse on day 5 of culture. CSF was induced by overnight stimulation with stimulator cells on days 4–5 of culture. The number of colonies (controls) with a standard CSF: 78±7, and NaCl: 0±0. Underlining indicates the presence of the *b* allele in the subregions of the *H-2* complex.

Figure 2 also shows that Meg-CSF and/or Eo-CSF and E-CSF were only found in supernatants which also contain GM-CSF. Possibly the colony-forming potential of CFC for megakaryocytes, eosinophils and erythroid cells is only expressed when stimulated by specific CSF and GM-CSF. This suggests that some supernatants might exist which only contain Meg-CSF and/or Eo-CSF and E-CSF but no GM-CSF and is compatible with data by Metcalf *et al.*[15]. Such supernatants would not be detectable in our standard assay. To investigate this we determined the CSF activity of one aliquot of a large number of supernatants from limiting dilution microcultures separately from another aliquot mixed with a standard CSF preparation from mouse lung conditioned medium (MLCM). This mixing experiment, however, gave no indication of the

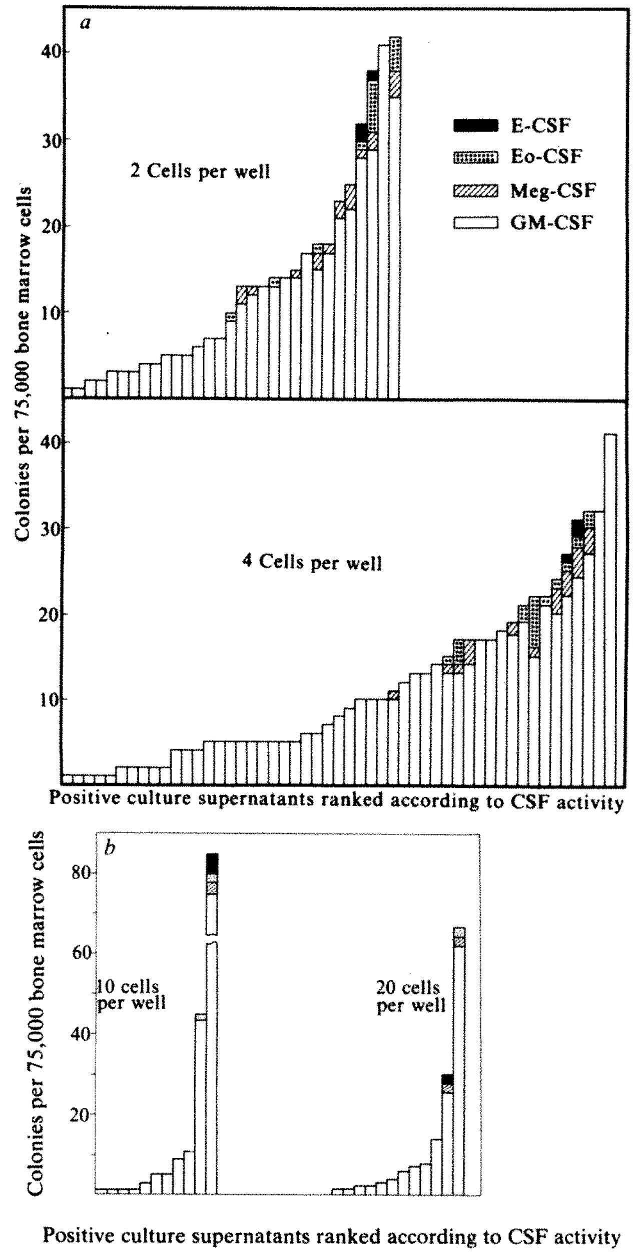

Fig. 2 *a*, Analysis of CSF types in CSF-positive culture supernatants. B6 splenic T cells were established in limiting dilution microcultures as described in Fig. 1 at an initial plating of two (upper) or four (lower) cells per well. The CSF-positive culture supernatants were ranked according to their activity. Number of colonies (controls) with a CSF standard: 84±5, and NaCl: 0±0. *b*, Analysis of CSF types in supernatants of T cells grown in limiting dilution microcultures in the presence of SRBC as filler cells. B6 splenic T cells were grown as described in Fig. 1 legend except that instead of irradiated allogeneic peritoneal exudate filler cells 10^6 SRBC from a selected batch particularly suitable for growth promotion were used as filler cells. Number of colonies (controls) with a CSF standard: 110±15, and NaCl: 0±0.

existence of supernatants containing only Meg-CSF and/or Eo-CSF and E-CSF, and the existence of potentiators or inhibitors of standard CSF in these supernatants could not be demonstrated (data not shown).

The above experiments suggest that different CSF types are produced by T cells. As T cells were plated in limiting dilution microcultures in the presence of allogeneic irradiated PEC it had to be excluded, however, that these PEC were involved in CSF production. Table 1 shows that no linear correlation could be found between the number of CSF-positive wells and the number of irradiated PEC used in the microculture system. In fact, at the highest number of PEC (10^5 per well) a decrease rather than an increase of CSF-positive culture supernatants occurred. In addition, when selected batches of sheep red blood cells (SRBC) instead of PEC were used as filler cells CSF production was still detectable. Although the growth frequency of T cells in these cultures was comparatively lower than with PEC as filler cells some supernatants contained very high levels of GM-CSF as well as the other CSF types (Fig. 2*b*).

CSF has recently been obtained from T-cell hybridomas[16]. That normal T cells produce CSF is supported by our experiments with TCGF-dependent cell lines in long-term cultures. Such lines and clones, however, might be aberrant with respect to karyotype, gene expression and regulation of their gene products but this may primarily be the case for T-cell clones growing in medium supplemented with TCGF[17]. Therefore, we have complemented our analysis of such clones with T-cell lines and clones growing in long-term culture in the presence of TCGF and antigen. Cells of this type were found to have a normal karyotype (M. Nabholz, personal communication). In addition, our T-cell lines in long-term culture have not shown TCGF-independent growth or tumorogenicity which may indicate a transformed phenotype. As these cells probably represent a highly selected population, results should be compared with those from analysis of T cells in limiting dilution. The following data are therefore in line with our limiting dilution analysis.

Three representatives of T-cell lines in long-term culture are shown in Table 2. PC-AKR clone 29, previously described to produce high amounts of immune interferon on Con A stimulation[18,19], has been passaged in permanent culture for over 18 months in the complete absence of antigen and adherent cells and in the presence of TCGF. The alloreactive AKR anti-B6 T-cell lines PK 7.1.1b and PK 7.1.2 grow in the presence of both TCGF and irradiated B6 stimulator cells[9,20,21]. PC-AKR clone 29 produced GM-CSF and Meg-CSF whereas both alloreactive T-cell lines and clones derived from them (data not shown) produced all four types of CSF after stimulation with Con A (Table 2). These results differed from previous reports where CSF production by continuous T-cell lines was found to be constitutive[22] or dependent on the presence of syngeneic accessory cells[23].

We further studied whether antigen-specific recognition is involved in triggering CSF release using the alloreactive AKR anti-B6 T-cell line PK 7.1.2. This line shows antigen-specific proliferation against stimulator cells from mice which carry the *b* allele in the *K* and *I–A* region of the *H–2* complex (Table 3). It can be seen from Table 3 that stimulator cells with the same *H–2* determinants as those that induce proliferation also induce CSF release.

In conclusion, our data indicate that a large proportion of T cells produce CSF on mitogen induction. CSF release is also triggered from T cells during specific antigen recognition. Accessory cells do not seem to be absolutely necessary for CSF production although they might have a potentiating physiological role. Furthermore, the supernatant of a single T-cell clone can contain different types of CSF. However, the production of Meg-CSF, Eo-CSF and E-CSF occurs only concomitantly with GM-CSF. This may indicate that the CSF genes belong to a gene family derived from a common precursor. Indeed, the different CSF types seem to have a striking biochemical similarity[24]. It is not yet clear whether in physiological conditions of induction of CSF release and of antigen-specific recognition all CSF types are always produced simultaneously or whether separate inductive signals trigger the release of different CSF types to assure a fine tuning of the formation of haematopoietic cells.

We thank Dr P. Dörmer for support, Drs U. Kees and P. Kisielow for critically reading the manuscript and A. Michnay, H. Broszeit and L. Wadeson for technical help.

Japanese wild mouse, *Mus musculus molossinus*, has duplicated immunoglobulin γ2a genes

Akira Shimizu, Yasushi Hamaguchi, Yoshio Yaoita, Kazuo Moriwaki*, Kyoji Kondo† & Tasuku Honjo

Department of Genetics, Osaka University, School of Medicine,

* National Institute of Genetics, Mishima, Japan
† Faculty of Agriculture, Nagoya University, Nagoya, Japan

The immunoglobulin heavy chain loci of the mouse contain eight tightly linked genes that encode the constant region (C) of the immunoglobulin heavy chains (H). As no recombination occurred within the immunoglobulin C_H gene loci among more than 3,000 crosses of mice[1–3], the mouse C_H genes were believed to be inherited as a set, designated the *Igh* haplotype. Recent molecular cloning experiments[4–9] have demonstrated that the organization of the mouse *Igh* loci of BALB/c (*Igh*^{a} haplotype) is 5′-$C\mu$-(4.5 kilobases [kb])-C_δ-(55 kb)-$C_{\gamma3}$-(34 kb)-$C_{\gamma1}$-(21 kb)-$C_{\gamma2b}$-(15 kb)-$C_{\gamma2a}$-(14 kb)-C_ϵ-(12 kb)-C_α-3′. The structural analyses of four C_γ subclass genes have shown that they are essentially identical in terms of lengths and locations of each of the structural and intervening sequences[6,10–12]. Comparison of the nucleotide sequences of the $C_{\gamma1}$, $C_{\gamma2b}$ and $C_{\gamma2a}$ genes has shown that limited portions of the C_γ gene are conserved between compared pairs of the C_γ genes[12]. The results imply that the nucleotide sequences of the C_γ gene segments have been exchanged by recombination among related clustered genes. Similar studies on the $C_{\gamma2a}$ genes of different haplotypes, *Igh*^{a} and *Igh*^{b}, have also suggested that these two types of $C_{\gamma2a}$ gene have undergone recombinational exchange of a part of the gene sequence[13]. These results imply, in contrast to the previous belief, that frequent recombinational events have taken place within the *Igh* loci and that their nucleotide sequences have been rearranged during evolution. Here we present direct evidence that a Japanese wild mouse, *Mus musculus molossinus*, contains duplicated $C_{\gamma2a}$ genes while the copy numbers of the neighbouring C_H genes, that is, the $C_{\gamma1}$, $C_{\gamma2b}$ and C_ϵ genes, remain constant. The results indicate that the duplicated $C_{\gamma2a}$ genes of *M. m. molossinus* arose from unequal crossing-over between homologous chromosomes.

During our evolutionary study of immunoglobulin C_H genes (Y.Y. and T.H., in preparation) we found that DNAs of the Japanese wild mouse *M. m. molossinus* had several extra restriction DNA fragments which hybridized with a $C_{\gamma2b}$–$C_{\gamma2a}$ probe, whereas DNAs of many laboratory strain mice had a single fragment for each C_γ gene (ref. 6 and Y.Y. and H.T., in

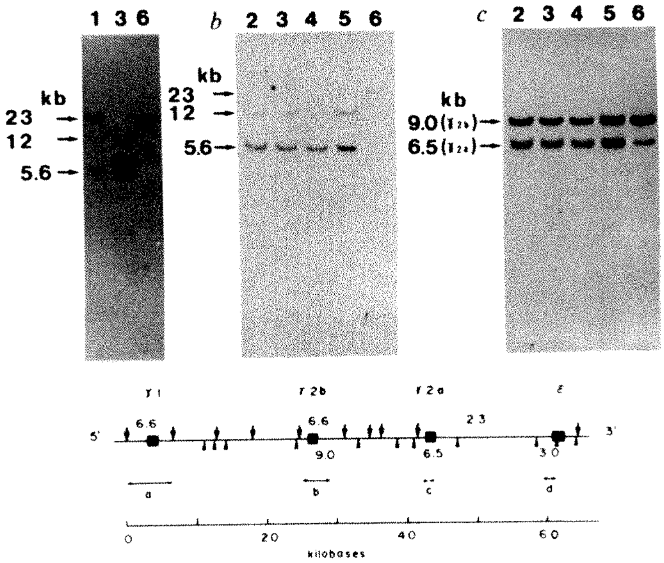

Fig. 1 Southern blot hybridization of *M. m. molossinus* liver DNA with $C_{\gamma2a}$ or $C_{\gamma2b}$–$C_{\gamma2a}$ gene probe. High molecular weight DNA was extracted from each individual liver of a wild heterozygous *M. m. molossinus* or inbred *M. m. molossinus* mice, or from livers of BALB/c mice as described previously[20]. We used three individual mice of inbred *M. m. molossinus* which are derived from wild mice trapped at Teine, Hokkaido Island. These mice are designated as Mol. Ten (individual numbers 101, 102 and 103). The other individual mouse of inbred *M. m. molossinus*, designated as MOL. A, is the progeny of wild mice trapped at Anjo, Aichi, Honshu Island. DNAs (1.5 μg each) were digested with *Eco*RI (*a*, *b*) or *Hin*dIII (*c*), electrophoresed in a 0.5% agarose gel and transferred to nitrocellulose filters as previously described[20,21]. Probes used are $C_{\gamma2a}$ (probe c) for *a* and *b* and $C_{\gamma2b}$–$C_{\gamma2a}$ (probe b) for *c*. Probes were labelled by nick-translation and hybridized as described elsewhere[20,22]. Origins of DNAs used are as follows: lane 1, a wild *M. m. molossinus*; lane 2, Mol. Ten 103; lane 3, Mol. Ten 102; lane 4, Mol. Ten 101; lane 5, MOL. A; lane 6, BALB/c. A restriction endonuclease cleavage map around the $C_{\gamma2a}$ gene of the BALB/c mouse and fragments used for probes are shown at the bottom. Data for the restriction map are taken from ref. 4. Structural genes are shown in closed boxes. Numbers above and below the top line indicate the sizes (kilobases) of *Eco*RI and *Hin*dIII fragments, respectively, which are described in the present study. Horizontal arrows under the top line indicate the fragments used as probes: a, 6.6-kb *Eco*RI fragment of γ1 gene[10]; b, 4-kb *Xba*I–*Hha*I fragment of $C_{\gamma2b}$ gene[11] which hybridizes to not only the $C_{\gamma2b}$ gene but also the $C_{\gamma2a}$ gene[4,20]; c, 217-base pair *Hae*III fragment of $C_{\gamma2a}$ gene which contains the 5′ 12 base pairs of the hinge region exon and the 3′ half of the intervening sequence between the C_H1 domain and the hinge region exons[12]; d, 2-kb *Bam*HI-*Hin*dIII fragment of C_ϵ gene[5]. ↓ and ▲ indicate *Eco*RI and *Hin*dIII sites, respectively.

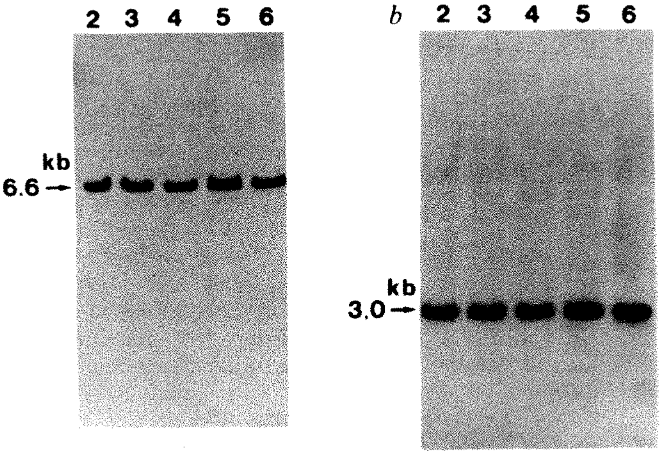

Fig. 2 Southern blot hybridization of *M. m. molossinus* liver DNA with $C_{\gamma1}$ or C_ϵ probe. DNAs (1.5 μg each) were digested with *Eco*RI (*a*) or *Hin*dIII (*b*) and electrophoresed, blotted and hybridized as described in Fig. 1 legend except that probes used are $C_{\gamma1}$ (probe a in Fig. 1) for *a* and C_ϵ (probe d in Fig. 1) for *b*. Origins of DNAs used in lanes indicated were the same as described in Fig. 1 legend.

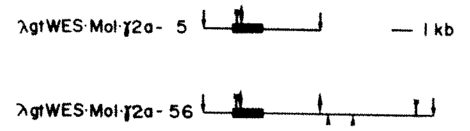

Fig. 3 Restriction map of two cloned $C_{\gamma 2a}$ genes of *M. m. molosssinus*. High molecular weight DNA of Mol. Ten 103 was digested with *Eco*RI to completion and the digests were fractionated by electrophoresis in a 0.5% agarose gel. Fragments of 5.6 and 12 kb were collected and ligated to λgtWES arms as described previously[9]. Ligated DNAs were packaged *in vitro* and screened with BALB/c $C_{\gamma 2b}$–$C_{\gamma 2a}$ probe (probe b in Fig. 1) as described elsewhere[4]. Two and three identical clones were isolated from 5.6- and 12-kb fragments, respectively. Inserts of λgtWES·Mol·γ2a-5 (5.6 kb) and λgtWES·Mol·γ2a–56 (12 kb) are shown by horizontal bars. Closed boxes indicate structure genes. Restriction enzyme cleavage sites are indicated as follows: ↓, *Eco*RI; ▲, *Hin*dIII; ◆, *Xho*I; ↑, *Bgl*I.

preparation). DNA of *M. m. molossinus* had four *Eco*RI fragments (12, 9.3, 5.6 and 1.85 kb) hybridizing with a $C_{\gamma 2b}$–$C_{\gamma 2a}$ probe in addition to the 23-kb $C_{\gamma 2a}$ and 6.6-kb $C_{\gamma 2b}$ fragments which are shared by BALB/c, C57BL and other inbred strain mice[6]. We used the $C_{\gamma 2b}$ gene fragment (probe b in Fig. 1) as a probe for both $C_{\gamma 2a}$ and $C_{\gamma 2b}$ genes. The $C_{\gamma 2a}$ gene fragments were usually less intense than the $C_{\gamma 2b}$ gene fragment because the $C_{\gamma 2a}$ gene sequence was detected by cross-hybridization to a part of the probe. As the 12- and 5.6-kb fragments were less intense than the 9.3- and 1.85-kb fragments, we presumed that the former fragments are the $C_{\gamma 2a}$ gene.

To determine unequivocally which of the above *Eco*RI fragments are the $C_{\gamma 2a}$ gene, we used as a probe the restriction DNA fragment that contains the 3′ half of the intervening sequence between the coding sequences for the C_H1 domain and the hinge region of the γ2a chain (probe c in Fig. 1). This probe has little cross-hybridization with the $C_{\gamma 2b}$ gene[12]. As shown in Fig. 1*a*, DNA of an individual *M. m. molossinus* mouse (which was trapped at Mishima, in Honshu Island) has three *Eco*RI fragments (23, 12 and 5.6 kb) that hybridize with the $C_{\gamma 2a}$ probe. The results seem to indicate that the $C_{\gamma 2a}$ gene is duplicated in this wild mouse, although the presence of heterozygous $C_{\gamma 2a}$ gene cannot be excluded.

We next examined DNAs of four individual mice of *M. m. molossinus* which have been maintained in laboratories by full-sibmating for 11 generations in the Mol. Ten strain and for 23 generations in the MOL. A strain. The Mol. Ten strain was derived from wild mice caught at Teine in Hokkaido Island and the MOL. A strain from those caught at Anjo in Honshu Island. *Eco*RI digestion of DNAs of these *M. m. molossinus* strains gave two DNA fragments (12 and 5.6 kb) which were identical for the two strains, whereas DNA of BALB/c mice had a single *Eco*RI fragment of 23 kb (Fig. 1*b*). The results strongly support the idea that *M. m. molossinus* has the duplicated $C_{\gamma 2a}$ genes, one of which is located in the 12-kb *Eco*RI fragment and the other in the 5.6-kb fragment. One can still argue the possibility, however, that *M. m. molossinus* has introduced point mutations which have created new *Eco*RI sites, thus converting the 23-kb fragment into the 12- and 5.6-kb fragments.

To exclude this possibility, we used another restriction enzyme, *Hin*dIII. *Hin*dIII digestion of *M. m. molossinus* produced the 9.0-kb $C_{\gamma 2b}$ fragment and the 6.5-kb $C_{\gamma 2a}$ fragment, both of which are identical in size to those of BALB/c DNA (Fig. 1*c*). However, 6.5-kb bands of the $C_{\gamma 2a}$ gene of *M. m. molossinus* DNAs are about twice as dark as that of the BALB/c DNA. In contrast, the intensity of the $C_{\gamma 2b}$ gene bands (9.0 kb) remains the same among DNAs of *M. m. molossinus* and BALB/c mice.

To examine whether neighbouring C_H genes are duplicated, we analysed the $C_{\gamma 1}$ and C_ϵ genes. As Fig. 2 clearly shows, the intensity and size of the $C_{\gamma 1}$ and C_ϵ genes in these wild mice are indistinguishable from those of BALB/c mice. We have also found that the $C_{\gamma 3}$ gene is not duplicated (data not shown). Previously we showed that the number of the C_μ and C_α gene fragments of *M. m. molossinus* are identical to those of many laboratory inbred strain mice although the sizes of the fragments vary slightly[6].

We have further cloned two DNA fragments, each containing a complete $C_{\gamma 2a}$ gene, from DNA of an individual *M. m. molossinus*. One $C_{\gamma 2a}$ gene is located in the 12-kb *Eco*RI fragment and other in the 5.6 kb *Eco*RI fragment (Fig. 3). The restriction sites in the cloned DNA fragments are consistent with those determined by Southern blot analyses.

These results demonstrate that *M. m. molossinus* has a new haplotype which contains the duplicated $C_{\gamma 2a}$ genes. In spite of the fact that these four mice are derived from two independent populations in different islands of Japan, the mice seem to have a similar haplotype, indicating that this haplotype is widely distributed among various local colonies of *M. m. molossinus*.

Lieberman and Potter[14] analysed allotype markers of serum immunoglobulins of homozygous *M. m. molossinus* (Kyushu) and found that this wild mouse had $IgG2a^a$ markers in addition to the $IgG1^b$, $IgG2b^b$, $IgG2a^b$ and IgA^b markers. They proposed that this haplotype is created by unequal crossing-over between the Igh^a and Igh^b haplotypes. Using monoclonal antibodies which can distinguish *a* and *b* allotypes, Herzenberg and his associates (personal communication) also found that two individual mice of inbred *M. m. molossinus* (Mol. Ten strain) have two allotypes of IgG2a, namely $IgG2a^a$ and $IgG2a^b$. Because the restriction sites around the coding regions of the $C_{\gamma 2b}$ and $C_{\gamma 2a}$ genes are well conserved between C57BL (Igh^b) and BALB/c (Igh^a)[6,9], we are unable to correlate the $C_{\gamma 2a}$ gene fragments with serological markers. The restriction map of the cloned $C_{\gamma 2b}$ gene of *M. m. molossinus* is different from those of BALB/c and C57BL (A.S. *et al.*, in preparation). As Fig. 4 shows, it is therefore likely that the duplicated $C_{\gamma 2a}$ genes of *M. m. molossinus* arose from unequal crossing-over between two different haplotypes which must be characterized and identified by nucleotide sequence determination.

Since immunoglobulin allotypes are distributed among various subspecies of *M. musculus*, the allotype seems to have evolved before the divergence of the subspecies of *M. musculus*.

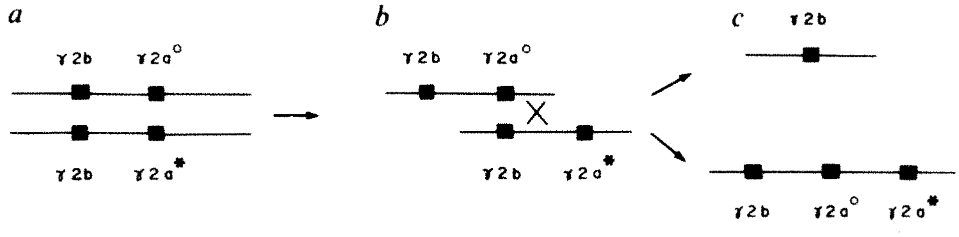

Fig. 4 A possible recombination that created duplicated $C_{\gamma 2a}$ genes with different allotypes. *a*, schematic representation of heterozygous mouse chromosomes containing two different $C_{\gamma 2a}$ genes. $\gamma_{2a}{}^*$ and $\gamma_{2a}{}^\circ$ indicate $C_{\gamma 2a}$ genes with different allotypes. *b*, Unequal pairing between homologues at meiosis and unequal crossing-over. As $C_{\gamma 2b}$ and $C_{\gamma 2a}$ genes have extensive homology[8,12], such a misalignment may occur at meiosis. *c*, Resultant chromosomes. In one chromosome (upper) the $C_{\gamma 2a}$ gene has been deleted, while the other chromosome contains the duplicated $C_{\gamma 2a}$ genes which have different allotypes. The latter chromosome may be an ancestor of the present chromosome in *M. m. molossinus*.

The duplication of the $C_{\gamma 2a}$ gene must have taken place after the divergence of *M. m. molossinus* and *M. m. domesticus*, an estimated one million years ago[15-17]. Duplication of immunoglobulin genes has also been suggested in humans by serological studies[18,19].

*Eco*RI digestion of DNA of the first heterozygous *M. m. molossinus* mouse produced three $C_{\gamma 2a}$ gene fragments (23, 12 and 5.6 kb) and three $C_{\gamma 2b}$ gene fragments (9.3, 6.6 and 1.85 kb). It is now clear that the 12- and 5.6-kb $C_{\gamma 2a}$ gene fragments are located on one chromosome and the 23-kb $C_{\gamma 2a}$ gene fragment on the other. We also know that the 6.6-kb $C_{\gamma 2b}$ gene fragment is derived from the chromosome containing the duplicated $C_{\gamma 2a}$ gene. Consequently, the other chromosome should contain two $C_{\gamma 2b}$ gene fragments (9.3 and 1.85 kb) and one $C_{\gamma 2a}$ gene (23 kb). It is not clear whether these two *Eco*RI fragments of the $C_{\gamma 2b}$ gene are due to the gene duplication or to the introduction of new *Eco*RI sites by point mutation.

The number of C_H genes has been thought to be invariant among inbred strains, although definitive proof is lacking. Previous studies (ref. 6 and Y.Y. and H.T., in preparation) using Southern blot analyses indicate the presence of a single gene for each of the C_μ . $C_{\gamma 1}$, $C_{\gamma 2b}$, $C_{\gamma 2a}$, C_ϵ and C_α genes in many inbred strains including BALB/c, C57BL, AKR, AJ, NZB and SJL. It may be safe to conclude that inbred strains mentioned above have similar sets of C_H genes although they have considerable divergence in the nucleotide sequence.

We thank Dr L. A. Herzenberg for providing us with unpublished data of allotype analyses and Miss F. Oguni for assistance in preparing the manuscript. This investigation was supported in part by grants from the Ministry of Education, Science and Culture of Japan, Torey Science Foundation, Mitsubishi Science Foundation and Naito Foundation.

Neurofibrillary tangles are a prominent feature in the pyramidal cells of the hippocampus and in neurones of the cerebral cortex of people suffering from senile dementia of the Alzheimer type (SDAT)[1]. Similar neuronal changes also occur in elderly Down's syndrome patients and to a lesser degree in intellectually normal old people[2]. The tangles are composed of bundles of paired helically twisted 10–13 nm filaments (PHF)[3,4], which may be either neurofilaments[3] or microtubules[5]. Attempts to isolate tangles from postmortem material have met with some success[6] but there is disagreement over the molecular weight (M_r) of presumptive PHF proteins enriched in these fractions, with conflicting claims of 50,000 (refs 6, 7) and 20,000 (ref. 8). Initially it seemed that the 50,000-M_r putative PHF protein and tubulin cross-react[9,10] but this result may have been a serological artefact, due to tangle-associated material in preparations of microtubule proteins used as immunogen and as test antigen[11]. We have used monoclonal antibodies to show here that neurofilament antigens are present in neurofibrillary tangles.

Monoclonal antibodies were produced as previously described using as immunogen either Triton X-100-insoluble rat brain protein[12] (monoclonal antibodies RT 97, RS 18, 147, 155) or a crude soluble protein fraction (1 h 150,000g_{av} supernatant) from two pooled hippocampi (SDAT cases U212 and U224, one of which was also studied immunohistochemically; see Table 2) (monoclonal antibody BF 10). Hybridomas secreting antibody to neurofilaments were screened as before[12] and to neurofibrillary tangles by the peroxidase–antiperoxidase (PAP) or by the indirect immunoperoxidase methods on paraffin sections of tangle-rich human brain[13]. Neuropathological samples were selected from postmortem brains of three

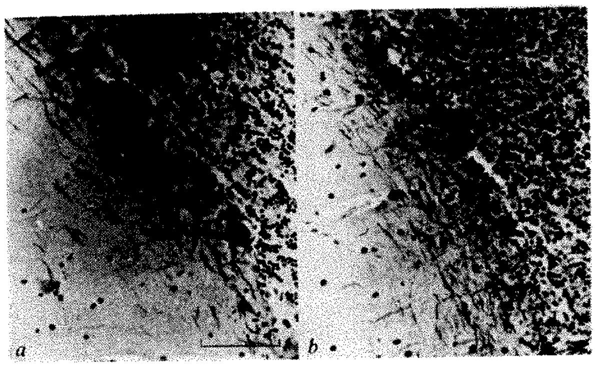

Fig. 1 Human cerebellum (paraffin sections) was stained by the PAP method[13]. *a*, Monoclonal antibody 147; *b*, monoclonal antibody BF 10 (counter-stained with Harris's haematoxylin). Baskets and neuronal fibres reacted strongly. Monoclonal antibodies were used both as tissue culture supernatants (undiluted) and as ascites fluid [diluted 1:1,000 with Tris-buffered saline, *p*H 7.6 (TBS)]. Normal horse serum (diluted 1:5 with TBS) was used instead of normal goat serum in the preincubation step to eliminate non-specific staining. After overnight incubation at ambient temperature with monoclonal antibodies, sections were washed in TBS (30 min), overlayed with rabbit anti-mouse IgG (H + L; Nordic) diluted 1:200 with TBS (30 min), washed in TBS (30 min), overlayed with goat anti-rabbit IgG (Fc fragment; Nordic) diluted 1:200 with TBS (30 min), washed in TBS (30 min), overlayed by PAP produced in rabbits (Miles) diluted 1:300 with TBS. The reaction was developed with diaminobenzidine (BDH). Scale bar, 100 μm.

cases of senile dementia of the Alzheimer type, one elderly Down's sydrome subject and one intellectually normal old subject. We found that five monoclonal antibodies (Table 1) resembled rabbit anti-bovine neurofilament 210,000-M_r polypeptide (anti-210K) sera previously described[13,14] in their reaction on human cerebellum, as they all reacted with basket cell axons around the Purkinje cells and neuronal fibres in the inner third of the molecular layer (Fig. 1). Monoclonal antibodies BF 10 and 147 and the rabbit anti-210K antiserum were found to react with some neuronal fibres in the cortex and subcortical white matter (Fig. 2*a*). BF 10 and RT 97 were the only antibodies to react with tangles, and did so in all cases studied (Tables 1, 2); the extent of reaction with tangles resembled that of similar slides after silver or Congo red staining. Initial studies of antibody RT 97 in tissue culture supernatants suggested that the antibody was not tangle reactive, but subsequent studies using ascites fluid showed that, like BF 10, it also stains tangles down to a dilution of ascites fluid of at least 1:2,000. Ascites fluid antibodies RS 18, 147 and 155 do not react with tangles even at 1:200 dilutions whereas all stain neurofilaments at 1:2,000 dilution. The ascites fluid was used at dilutions of at least 1:2,000, as, if more concentrated, background staining of sections becomes appreciable.

PHF can be associated with neuronal perikarya in the form of neurofibrillary tangles or with certain neurites in plaques. As well as staining tangles, BF 10 and RT 97 reacted strongly with numerous distended terminals or neurites which constitute the major part of the senile plaque (Fig. 2*c–e*). In case T/B, BF 10-positive material was found associated with plaques and only an occasional perikaryon (Fig. 2*f*); RT 97 was not studied in sufficient detail to know whether it reacted identically with BF 10 in this case. Only a minority of the neurites in plaques reacted with antibodies other than BF 10 and RT 97 (Fig. 2*b*; Table 1) and none of the antibodies stained amyloid. These results are consistent with our earlier observations of the lack of tangle-reactivity of rabbit anti-bovine neurofilament sera[13]. Absorption of BF 10 with purified bovine neurofilaments (polypeptide pattern shown in Fig. 3*a*) removed all staining with this antibody.

The monoclonal antibodies were analysed by immunoblotting[15] on purified bovine neurofilaments and on total protein from SDAT and control human hippocampi (Fig. 3). BF 10 and 155 react predominantly with the 155,000-M_r neurofilament protein of bovine neurofilaments and the corresponding polypeptide in human brain. RT 97, 147 and RS 18 bind most strongly to the 210,000-M_r bovine neurofilament protein and the equivalent human polypeptide. Several of the monoclonal antibodies seem to cross-react[14,16,17] with the 210,000- and 155,000-M_r neurofilament proteins. BF 10 reacts with both the 155,000- and 210,000-M_r polypeptides of bovine neurofilaments (Fig. 3*b*) but is specific for the 155,000-M_r polypeptide of human neurofilaments (Fig. 3*g*, *n*). RT 97 also seems to react with both polypeptides in bovine neurofilaments (Fig. 3*d*) but in human material may be specific for the 210,000-M_r protein (Fig. 3*i*, *p*). RS 18 (Fig. 3*e*, *j*, *q*) reacts similarly to RT 97 but 147 seems specific to the 210,000-M_r polypeptide of both bovine and human neurofilaments (Fig. 3*c*, *h*, *o*). Monoclonal antibody 155 is specific for the 155,000-M_r polypeptide in both species but reacts strongly with several lower molecular weight (50,000–60,000) bands (Fig. 3*f*, *k*, *r*). Antibody BF 10 also reacts strongly with two to four bands just below the 155,000-M_r polypeptide. We have tentatively attributed these extra bands to proteolytic degradation of the major neurofilament proteins; if this is the case, the corresponding antigenic determinants are probably well separated in the 155,000-M_r polypeptide. Other bands, which can be visualized on longer exposure of autoradiographs with all the antibodies (data not

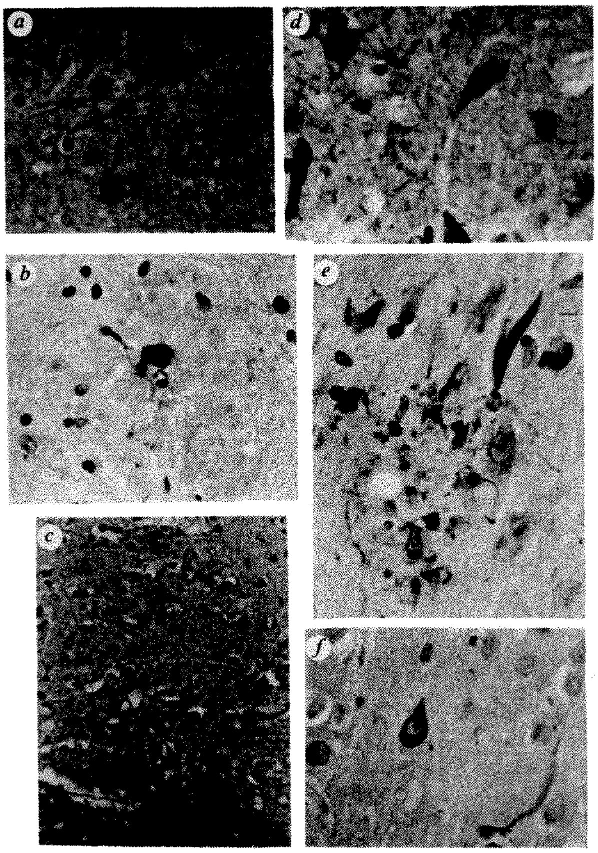

Fig. 2 Reaction of plaques and tangles with monoclonal antibodies 147 and BF 10. *a*, T/A fibres in cortex reacting with 147 (scale bar, 50 μm; applies to *a*, *b*, *d–f*); *b*, U/144 neurites in a plaque reacting with 147; *c*, T/A tangles in pyramidal cells in cortex reacting with BF 10 (scale bar, 100 μm); *d*, U/303 tangles in pyramidal cells of hippocampus reacting with BF 10; *e*, U/144 tangles and neurites in a plaque reacting with BF 10; *f*, T/B tangles in a pyramidal cell perikaryon reacting with BF 10.

Table 1 Immunohistochemical reaction pattern and antigenic specificities of antibodies

Clone	Immunoglobulin subclass	Reaction with neurofibrillary tangles	Reaction with human senile plaques	Reaction with human neurofilaments*	Neurofilament polypeptide with major antigenic determinant (M_r)
BF 10	IgG2a	+	N	+	155,000
RT 97	IgG1	+	N	+	210,000
RS 18	IgG1	–	n	+	210,000
147	IgG1	–	n	+	210,000
155	IgG1	–	n	+	155,000
BF 10-absorbed	–	–	–	–	ND
Rabbit anti-210K neurofilament sera	–	–	n	+	210,000, 155,000

N, most neurites; n, occasional neurites. ND, not determined.
*Determined by characteristic staining pattern on cerebellum.

Table 2 Comparison of immunohistochemical reaction pattern of two monoclonal antibodies on five different postmortem specimens

Case		Area examined	BF 10	Reaction pattern 147, rabbit anti-210K antiserum
U/224	(SDAT)	DG, H	T, N	n
U/303	(SDAT)	DG, H	T, N	n
T/A	(SDAT)	NC, SWM	T, N, A	n, A
U/144	(Down's syndrome)	DG, H	T, N	n
T/B	(old age)	NC, SWM	T, N, A	n, A

DG, dentate gyrus; H, hippocampus; NC, neocortex; SWM, subcortical white matter. T, neuronal perikaryal tangles; A, axons; N, most neurites in senile plaques; n, occasional neurites in senile plaques.

shown), are being investigated. Immunoblotting did not reveal any outstanding differences between normal and SDAT neurofilament antigens with any of the antibodies used, including BF 10 and RT 97. Differences such as the relative sharpness and intensities of individual bands are probably the result of postmortem degradation and variability in the efficiency of blotting and would only be significant if confirmed in analyses of many different postmortem specimens. The neurofilament proteins detected by the antibodies on the immunoblots are minor constituents of the total human hippocampal proteins present as neurofilament bands in the stained tracks (Fig. 3*l*, *m*) are not obviously visible; this attests to the sensitivity and specificity of the antibodies for immunochemical analysis of neurofilament antigens (neurofilaments are only a minor component of the total protein composition of grey matter even of fresh rat brain although white matter is relatively rich in neurofilaments).

Neurofibrillary tangles must share at least two antigenic determinants with neurofilaments as the immunoblots analysis has shown RT 97 and BF 10 to be clearly directed at different sites of the neurofilament structure and possibly different neurofilament polypeptides (Table 1). Some tangles contain a mixture of apparently normal neurofilaments and PHF[18,19] and are occasionally composed of bundles of straight filaments (B.E.T., unpublished) but the strength of the reaction with the BF 10 and RT 97 monoclonal antibodies with most of the tangles suggests that the reactive component is not simply due to inclusions of neurofilaments. Ultrastructural studies with this antibody are required to confirm this. As other monoclonal antibodies and rabbit antisera which react with normal human neurofilaments fail to stain tangles, any neurofilaments present in the PHF (or straight filaments) must be structurally different. The differential reactivity of RT 97 in tissue culture supernatants with tangles and normal neuronal fibres suggests that the corresponding antigenic determinant may be partially affected in tangles resulting in a failure of RT 97 to bind when the antibody concentration is low. The pattern of reactivity with the panel of antibodies is consistent for all tangles of a given case and for all five cases studied (three SDAT, one Down's syndrome, one normal old age), which implies that any change in neurofilament integrity is a precisely defined event and not a random breakdown of structure. Immunoblotting so far has failed to reveal any gross differences in molecular weight of neurofilament antigens from control and SDAT tissues and suggests that an altered antigenicity may be the result of either an intrinsic conformational change in the filament protein or a different packing and/or masking of antigenic determinants. BF 10 and RT 97 monoclonal antibodies should be useful new reagents for probing the chemical composition of neurofibrillary tangles.

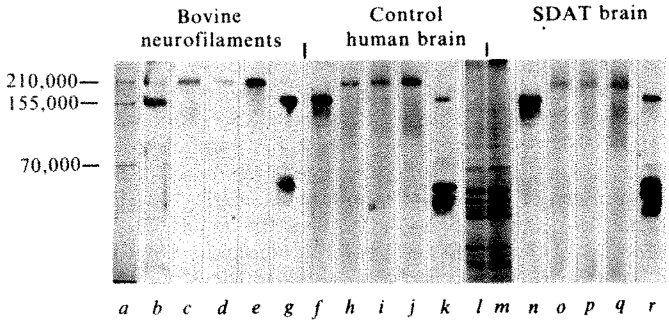

Fig. 3 Immunoblots showing the antigenic specificities of all five monoclonal antibodies on isolated bovine neurofilaments (*a–f*); total hippocampal proteins of control human brain (*g–l*); total hippocamal proteins of SDAT brain (*m–r*). *a*, *l*, *m* Are stained with Coomassie brilliant blue and are tracks cut from SDS slab gels[22]. The remainder of the tracks, with identical sample loadings, were blotted and processed essentially as according to Towbin *et al.*[15] on to nitrocellulose sheets which were then cut into strips and each strip incubated with a different antibody followed by ^{125}I-labelled rabbit anti-mouse immunoglobulins. The autoradiographs are aligned exactly with the stained gel strips to show the position of the labelled antigens present in the total sample proteins. BF 10 (*b*, *f*, *n*); 147 (*c*, *h*, *o*); RT 97 (*d*, *i*, *p*); RS 18 (*e*, *j*, *q*); 155 (*g*, *k*, *r*). Ascites fluid for the incubations with the nitrocellulose blots was diluted as follows: BF 10—$1:10^2$ (*b*), $1:5\times10^4$ (*f*, *n*); 147—$1:4\times10^3$ (*c*), $1:10^4$ (*h*, *o*); RT 97—$1:1.5\times10^3$ (d), $1:2\times10^4$ (i, p); RS 18—$1:2\times10^3$ (*e*), $1:5\times10^3$ (*j*, *q*); 155—$1:2\times10^3$ (*g*), $1:5\times10^3$ (*k*, *r*). The molecular weight of the individual bovine neurofilament triplet polypeptides are indicated at the left-hand side.

This work was supported by the Wellcome Trust and the MRC. We thank Dr L. H. Carrasco, Professor J. A. N. Corsellis, Dr B. Doshi, Dr I. Janota and Professor P. L. Lantos for advice and assistance in collecting specimens, and Dr R. Calvert for preparations of isolated bovine neurofilaments.

Note added in proof: Selkoe *et al.*[20] have claimed that PHF are insoluble in SDS which would therefore make it difficult to analyse these proteins by SDS-gel electrophoresis and immunoblotting. This same group[21] have also recently published evidence that the 20,000-M_r protein previously found to be enriched in the PHF fraction[8] is, in fact, myelin basic protein.

A model for the molecular requirements of immunoglobulin heavy chain class switching

Kenneth B. Marcu, Rhonda B. Lang, Lawrence W. Stanton & Linda J. Harris

Biochemistry Department and Molecular Biology Graduate Program, State University of New York, Stony Brook, New York 11794, USA

Heavy chain immunoglobulin gene expression requires two independent DNA recombination systems[1-3]. The first DNA rearrangement event (V–D–J recombination) involves the formation of a complete variable region (V_H) gene in pre-B lymphocytes[3-6]. The second series of recombination events allows for a switch in heavy chain constant region class from μ to either $\gamma3$, $\gamma1$, $\gamma2b$, $\gamma2a$, ε or α[1-3]. These recombination events occur in intervening sequences but do not alter or generate new coding information which is a common feature of V–D–J unions[1-3]. Tandemly repeated DNA sequences, spanning ~2–5 kilobases (b), are localized ~1.5 kilobase pairs 5′ of each C_H gene and have been termed C_H switch (S) regions[2,7]. Two short, simple sequences that are shared by all switch region repeats (GAGCT and GGGGT) have been proposed to facilitate C_H switching by homologous DNA recombination[8]. Unlike other switch regions, a large portion of the S_μ region (3 kb) consists of essentially pure tandem repeats of GAGCT which are occasionally interrupted by a GGGGT[8]. However, the precise sites of switch-recombination in S_μ are generally located considerably 5′ of this genetically unstable stretch[9,10] of GAGCT repeats (Fig. 1). We now report the properties of a novel C_H S region sequence, YAGGTTG, which is 5′ of switch recombination sites and preferentially repeated in S regions.

The nucleotide sequences in the immediate vicinity of the switch-recombination sites used by 10 rearranged C_H genes are depicted in Fig. 2. Germ-line S_μ sequences are all referred to as 'donor sites' because all functional switch events must originate 5′ of the C_μ gene and then for simplicity all other germ-line S_H sites are termed 'acceptors'. Acceptors may also serve as donors when multiple recombination events result in a functional switch. Abortively rearranged C_H genes can either be generated by inter-switch region acceptor recombinations (that is, as with $S_{\gamma3}$ and $S_{\gamma2b}$ in MPC11)[11] or by the recombination of non-immunoglobulin-associated DNA sequences (that is, non-switch region DNA) with an S_H region[12,37,38]. The only common feature at or near all the recombination sites shown in Fig. 2 is the presence of a prevalent heptamer sequence, YAGGTTG. Several expressed C_H genes use an analogue of YAGGTTG in the identical sequence environment, suggesting that these may constitute preferred switch sites. Analogues of this prevalent heptamer are occasionally located 3′ of some of these recombination sites. However, GAGCT and GGGGT sequences are absent in 9 of these 21 DNA sequences. The poorest YAGGTTG analogues (4/7 matches) are utilized by the $S_{\gamma2b}$ acceptor in MOPC 141 and the S_μ donor of MC101 (a $\gamma1$ producer). However, the four matched nucleotides are contiguous in both cases. Therefore, we assume that the minimum criterion for a YAGGTTG sequence analogue is a 4/7 match with four contiguous matched nucleotides. As most of these putative recognition sequences are not perfect matches to a YAGGTTG heptamer, we analysed other properties of YAGGTTG-like sequences which might support the idea of their specific involvement in the C_H switching mechanism.

The majority of switch events appear to occur 8–16 nucleotides 3′ of this common sequence (Fig. 3). However, four of the rearrangement events shown in Fig. 2 occur within this prevalent sequence. Two of these examples are acceptor sites of abortively rearranged genes ($\gamma2b$ in MPC11, and α in MOPC 603)[11,12]. One of these events occurred within intervening sequence (IVS) I of the $C_{\gamma1}$ gene which resulted in a C_H1 domain deletion[13]. The fourth and last case ($\gamma2b$ in MOPC 141) occurred 1.0 kb beyond the 3′ boundary of the repetitive $S_{\gamma2b}$ acceptor region[3,14]. The expressed $\gamma2b$ gene in MOPC 141 is the only known example of a switch that occurs beyond the 3′ boundary of a repetitive switch region. We have failed to observe a reoccurrence of this rare event in any of 13 different $\gamma2b$-producing plasmacytomas (R.B.L. and K.B.M., in preparation). The significance of the preference for 8–16 nucleotides between a YAGGTTG analogue and the actual switch site will require further confirmation from analyses of other functionally switched C_H genes.

YAGGTTG analogues are repeated in switch regions. Twenty-eight YAGGTTG-like sequences are located in the

Table 1 YAGGTTG (Y = CorT) matches in five switch regions of heavy chain constant region genes

Switch region	Length (kb)	YAGGTTG matches $\frac{7}{7}$	$\frac{6}{7}$	$\frac{5}{7}$	$\frac{4}{7}$	Total	Prevalent matches to YAGGTTG						
S_μ	5.20	1	8	8	15	32	Y 71	A 53	G 82	G 100	T 82	T 88	G 82
$S_{\gamma3}$ 5′	0.56	0	5	3	8	16	Y 100	A 88	G 88	G 100	Y 75	T 63	G 63
$S_{\gamma3}$ 3′	0.85	3	9	21	7	40	Y 88	A 88	G 100	G 100	Y 70	T 58	G 67
$S_{\gamma1}$	0.59	1	4	5	12	22	C 90	A 100	G 100	G 100	Y 80	T 80	G 50

Totals	10.2 $S_D = 5.2$ $S_A = 5.0$	11	70	58	65	204	Y 86	A 83	G 96	G 100	Y 80	T 71	G 76
C_H coding regions* (without IVS I)	6.8	0	3	40	72	115	Y 88	A 78	G 95	G 100	T 70	N	N

The minimum criteria for a match is 4/7 with all four nucleotides contiguous and all other matches (that is, 7/7, 6/7, 5/7) must also have four contiguous nucleotides. The switch region lengths only refer to sequenced DNA S_μ[3,8], $S_{\gamma3}$ 5′[11], $S_{\gamma3}$ 3′[27], $S_{\gamma1}$[11] $S_{\gamma2b}$[11] and S_α[7]. Prevalent matches to YAGGTTG were determined by only tabulating the 7/7, 6/7 and 5/7 matches. 4/7 matches only seem to be rarely used in functional C_H genes (Fig. 2) and the high probability to detect randomly such a non-specific match (a 1/51 chance) tends to randomize unnecessarily the resultant consensus sequences. The fit of a particular nucleotide is indicated as the percentage of its incidence in all 7/7, 6/7 and 5/7 matches combined. S_D refers to the entire S_μ region and S_A refers to all other S regions

* Data obtained from C_μ[28], $C_{\gamma1}$[29], $C_{\gamma2b}$[30 31], $C_{\gamma2a}$[32] and C_α[33] with IVS I contribution removed. N, any of the four nucleotides

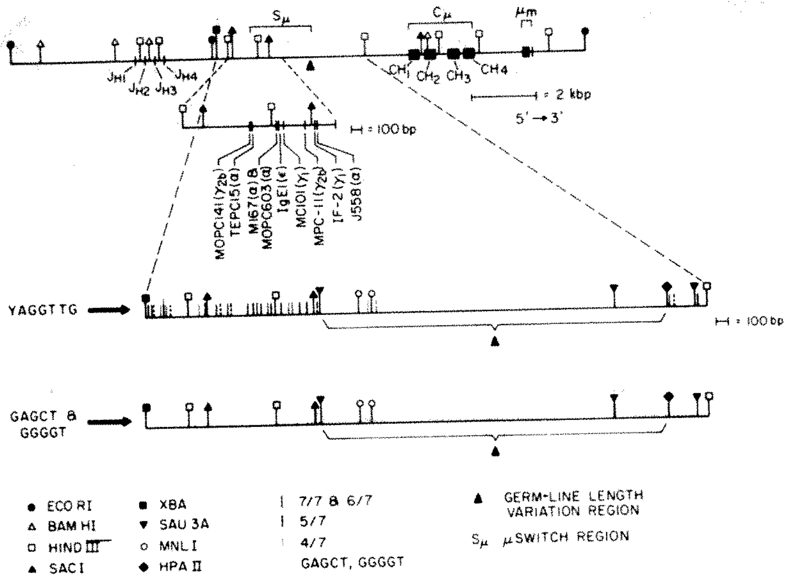

Fig. 1 The relative locations of C_H gene switch sites and two classes of hypothesized recognition sequences are indicated 5' of the mouse C_μ gene. Y represents a C or a T. The nucleotide sequence of the S_μ region were extracted from other publications[3,8]. The location of the unstable S_μ length variation region that consists of a relatively pure stretch of GAGCT and GGGGT sequences was determined from other published work[9,11] as well as our unpublished data. MOPC 141 (refs 3, 14), TEPC 15 (ref. 7), M167 (ref. 34), MOPC 603 (ref. 7), Ig E1 (ref. 8), MC101 (ref. 35), MPC 11 (ref. 36), IF-2 (ref. 14) and J558 (L.H. and K.B.M., in preparation).

immediate vicinity of all known S_μ sites used in C_H gene switches and S_H acceptor regions contain numerous repeats of YAGGTTG-like sequences (Table 1). Consensus sequences prepared for YAGGTTG analogues found in different switch regions closely resemble the YAGGTTG prototype sequence. Analogues of this recognition sequence are at least as prevalent as the common GAGCT sequences[8]. The S_α region is particularly rich in YAGGTTG-like sequences possessing 36 out of 54 examples that are either 7/7 or 6/7 matches in only 1,400 base pairs[7].

YAGGTTG sequences are not repeated in C_H coding regions. If similar amounts of C_H coding DNA (8.3 kb) and C_H switch region DNA (10.2 kb) are compared, the C_H coding regions are found to contain less than 10% of the total number of 7/7 and 6/7 YAGGTTG matches found within all switch regions (Tables 1, 2). The distribution of YAGGTTG analogues in C_H coding regions is below random expectations (Table 2). Indeed, these sequences are present in random amounts in three mouse globin genes[15,16] and in the entire J_K–C_K locus[17,18]. A lower frequency of YAGGTTG-like sequences in C_H coding regions may be selected for to avoid aberrant recombination events. More than 50% of the best YAGGTTG matches, that are found in C_H coding regions, occur in IVS I. If these are excluded from the C_H coding region analysis, the 3' end of the YAGGTTG-like heptamer appears random and gives a poor YAGGYNN composite (Table 1). These observations may be relevant to the phenomenon of rare C_H domain deletions in defective or mutant chains in mice[19] and humans[20]. Unlike the results observed for the entire C_H coding region, the presence of YAGGTTG analogues in IVS I agrees well with random expectations (Table 2).

Table 2 Observed frequencies of YAGGTTG sequences compared with their expected random frequencies

	No. YAGGTTG matches 7/7	6/7	5/7	4/7
C_H coding regions (8.3 kb)	0 (1)	6 (14)	58 (81)	105 (163)
C_H IVS I only (~1.5 kb)	0 (0)	3 (3)	18 (15)	33 (30)
C_H coding regions without IVS I (6.8 kb)	0 (0.8)	3 (12)	40 (67)	72 (133)
BALB/c α- and β-type globin genes (~5.0 kb)	3 (0.6)	18 (9)	51 (49)	87 (98)
Within 50 bp 5' of J_K and J_H (0.450 kb)	0 (0)	3 (0.8)	8 (4)	15 (9)
S_μ (without GAGCT repeat region; 2.2 kb)	1 (0)	9 (4)	17 (22)	30 (40)
All S regions (without S_μ GAGCT repeat region; 7.2 kb)	11 (1)	81 (12)	139 (70)	202 (140)

The total number of each of the four different categories for YAGGTTG matches are compared with their number derived from random expectations. The random probabilities used for 4/7, 5/7, 6/7 and 7/7 matches to YAGGTTG are 1/51, 1/102, 1/585 and 1/8192 respectively. Statistical probabilities were calculated with the assumption that the four matched nucleotides in the YAGGTTG sequence must be contiguous. Numbers in parentheses indicate the random expectation for the YAGGTTG analogue in a similar size sequence. YAGGTTG analogues were also observed to be random in the J_K–C_K and J_H loci and in the μ–δ intragenic region. C_H coding regions[28–33], BALB/c α- and β-type globin genes[15,16], J_K locus[17,18], J_K–C_K intragenic region and C_K[27], J_H locus[3], S_μ[3,8], other S regions[7,11,27].

We have compiled here considerable evidence for the involvement of a YAGGTTG-like sequence in the mechanism of C_H switch-recombination: (1) YAGGTTG-like sequences are predominant features of all functional switch sites so far identified. (2) YAGGTTG is 5' of the switch sites of both donor and acceptor sites for all C_H switches in a total of 21 examples. (3) Switch-recombination sites preferentially occur 8–16 nucleotides 3' of a YAGGTTG analogue. (4) YAGGTTG-like sequences are preferentially repeated in all S_H acceptor regions but appear unique to the S_μ donor region. (5) YAGGTTG analogues are present below random expectations in C_H domains and their IVSs except IVS Is.

As a model for C_H switch-recombination, we suggest that a YAGGTTG sequence or its close analogue acts with tandem repeats of a GAGCT sequence to mediate an efficient C_H gene switch. The S_μ donor region appears different and not only seems to require a YAGGTTG-like sequence close to the 5' side of the switch site but also to possess a very large region of GAGCT tandem repeats located considerably 3' of the actual switch site. The presence of 3 kb of GAGCT repeats in S_μ[8], the conservation of this repetitious region in mice and humans[21–23] and the existence of GAGCT and GGGGT in switch region consensus sequences[8] collectively argue that YAGGTTG analogues, as well as GAGCT repeats, are required for an efficient C_H switching process. The need for repeats of both YAGGTTG analogues as well as GAGCT and GGGGT sequences in switch acceptor regions may reflect the pairing process that allows for the proper alignment of C_H genes for an accurate switch event. After the initiation of this pairing event, a switch could perhaps occur close to any YAGGTTG analogue. However, this idea would not rule out that low-frequency switching events may not require the GAGCT epeats. This would be the case for the γ2b gene in MOPC 141 and the C_H1 domain deleted γ1 gene in IF-2 in which the switch acceptor sites have no GAGCT repeats. When considering recombination events associated with immunoglobulin genes, one must also be aware that rare V–J recombinations can occur with the participation of a conserved heptamer sequence in the absence of a nanomer sequence[18,24].

We consider this a working hypotheses which may stimulate further studies on C_H switch sites. The examination of other switch recombination events may confirm the role of the YAGGTTG-like sequences. One testable prediction of our model would be that C_H switches occurring in tissue culture variants of myeloma cell lines[25] utilize YAGGTTG analogues. A γ2b→γ2a switch in an MPC 11 switch variant has recently been shown to result from a DNA deletion event which encompasses the switch site of the γ2b-producing, parental MPC 11 cell and the entire γ2b-coding region[26]. We suggest that the endpoints of this deletion event may occur close to the 3′ side of YAGGTTG analogues. This type of secondary or variant cell switch would be an infrequent or rare event since the S_μ GAGCT repeat region is completely deleted on forming the original functional MPC 11 γ2b gene and is therefore unavailable for the secondary switch event. A direct functional test of the molecular requirements for C_H switching could use a gene transfer approach that would use B lymphocytes or switch variant myeloma cells as recipients of genetically modified, multi-C_H gene substrates whose germ-line switch regions have been deleted or specifically mutagenized.

Renin, a protease which cleaves the prohormone angiotensinogen, releasing angiotensin I, has a major role in regulating blood pressure and electrolyte balance. However, the primary structure and the active structure of the enzyme remain unknown. The presence of an inactive form of the enzyme, activable by partial proteolysis, has led to the proposal that renin is synthesized as an inactive precursor[1]. Kidney juxtaglomerular cells constitute the principal source of renin, but its concentration in this tissue is too low to allow determination of its primary structure by conventional techniques. In some strains of mice, the male submaxillary glands synthesize and secrete very large amounts of an enzyme which appears indistinguishable from renal renin by immunological and physicochemical criteria[2,3], thereby representing a unique opportunity to delineate the detailed features of renin. We now present the analysis of bacterial DNA recombinant clones harbouring an essentially complete transcript of renin mRNA isolated from the mouse submaxillary gland. The deduced amino acid sequence shows that renin is synthesized as a 44,209 molecular weight (M_r) precursor. Comparison with other known acid proteases shows a good alignment of renin and acid protease sequences in the neighbourhood of residues involved in the active site. N-terminal sequence analysis of renin reveals that the precursor is converted by a protein cleavage into active renin consisting of two chains of M_r 35,000 and 3,000.

We have previously described the construction of cDNA clone pRn5.3 which contains ~1,100 nucleotides of a mouse renin mRNA sequence[4]. The presence of a poly(A) extension at one end of pRn5.3, as revealed by nucleotide sequence analysis, indicated that the cDNA sequence in this clone corresponds to the 3′ portion of renin mRNA. A clone, designated pRn4.7, containing a sequence 5′ upstream of pRn5.3 cDNA, has been isolated (see Fig. 1 legend), and contains ~1,250 nucleotides of renin mRNA sequence. As clones pRn5.3 and pRn4.7 share an identical segment of ~900 nucleotides in their central portion and as pRn5.3 codes for the 3′-terminal region of renin mRNA, together they harbour an essentially complete transcript of renin mRNA. The nucleotide sequence of cDNA inserts was determined using the partial chemical degradation method of Maxam and Gilbert[5] in conditions previously described[6]. The strategy for sequencing pRn5.3 and pRn4.7 plasmids is presented in Fig. 1*a*, while Fig. 1*b* shows the nucleotide sequence of cDNA in pRn5.3 and pRn4.7; the sequence is 1,424 nucleotides long.

The sequence bears one open reading frame of 1,203 nucleotides, the two other reading frames containing, respectively, 17 and 20 nonsense codons. A search for the ATG translation initiating codon in the open reading frame near the beginning of the 5′ region revealed two ATG codons located 41 and 56 nucleotides from the 5′-terminal region of pRn4.7 cDNA. If the first ATG codon is the starting codon, the amino-terminal sequence of renin precursor would contain 3 basic residues followed by 10 hydrophobic amino acids. Such a sequence is very similar to the signal sequences observed at the amino-terminal end of most precursors of secreted proteins[7], making it likely that the first ATG codon is the starting codon.

As the endoprotease responsible for the cleavage of signal segments splits the peptide bond on the carboxy-terminus side of small uncharged amino acids and as the residues located in the neighbourhood of the cleavage site exhibit a high potential for making β-turns or aperiodic conformations[8], we propose that the cleavage site for preprorenin probably lies after Cys 18. However, two other cleavage sites—after Ser 21 and Gly 25—cannot be ruled out.

The coding sequence of renin mRNA is 1,203 nucleotides long and ends with the translation stop codon UAA. The deduced amino acid sequence gives a molecular weight for the renin precursor of 44,209. The 3′-untranslated region, which is 180 nucleotides long, contains four more potential stop codons in the same reading frame. The consensus sequence proposed by Proudfoot *et al.*[9] AATAAA, occurred 12 nucleotides before the polyadenylation site.

Enzymatic studies have shown that renin shares certain catalytic features with acid proteases[10,11]. James *et al.*[12] have proposed a mechanism for the catalytic hydrolysis of peptide bonds by acid proteases involving the proton shared by Asp 32 and Asp 215 of penicillopepsin as the electrophilic component and Tyr 75 as a charge relay element. These authors have shown that, on substrate binding, Tyr 75, originally bound to Trp 39, is involved in a conformational change.

We aligned the primary amino acid sequences of some pepsin family proteins—bovine and porcine pepsinogens[13,14], bovine prochymosin[15] and pepcillopepsin from *Penicillium janthinellum*[16]—with the renin sequence so as to maximize the homology between proteins. As calculated from Fig. 2, a homology of 37–24% exists between these acid proteases and renin. In particular, the cysteine residues occur within the renin chain at almost identical positions to those in the pepsinogen chain, suggesting the same arrangement of the disulphide bridges, and similarities in tertiary structure for renin and acid protease molecules.

Figure 2 shows that the two regions of highest homology between renin and acid proteases are those surrounding the two renin aspartyl residues Asp 101 and Asp 286, corresponding to Asp 32 and Asp 215 of penicillopepsin. Furthermore, the two residues Tyr 75 and Trp 39 are conserved, occurrring, respectively, at positions 146 and 108 of the renin chain. As mechanistic features of proteases indicate that the ways in which residues of a protein attack peptide bonds are limited, this homology in the active site of renin suggests a detailed analogy in catalytic mechanism. Our results thus indicate that renin and acid proteases have arisen by a process of divergent evolution from a single ancestral prototype[17].

To establish the relationship between the renin precursor and the mature active enzyme, we have determined the N-terminal sequence of pure active renin[18]. Although renin appeared homogeneous on analytical HPLC and SDS-gel electrophoresis, a double sequence was obtained. After reduction by mercaptoethanol, the molecular weight shifted from 38,000 to 35,000 and a faint band appeared at the front of the gel. A similar observation was reported by Suzuki *et al.*[19]. The double sequence and the decrease in molecular weight following reduction suggested that renin exists as two chains linked by a disulphide bridge. Therefore, renin was reduced, carboxymethylated and the two chains separated by gel filtration and subjected to automated Edman degradation; their N-terminal sequences are shown in Fig. 3.

The N-terminal sequence of peptide A, corresponding to the main protein band, determined for 21 positions, coincides with the portion of renin starting at position 64, and the sequence of peptide B, corresponding to the minor band, determined for 21 positions, coincides with the portion of the enzyme starting at position 354. We propose the model of renin processing shown in Fig. 4. The peptide signal is first removed from the renin precursor by membrane processing enzymes, leading to

Fig. 1 *a*, Bacterial cloning and sequencing strategy of recombinant plasmids. Comparison of renin mRNA size, ~1,600 nucleotides as determined previously[4], and 1,100-nucleotide cDNA insert in pRn5.3 shows that ~400 nucleotides are required to complete the sequence of the renin message (if we assume that the poly(A) track is 100 nucleotides long). To clone the 5′ portion of renin mRNA, partially purified renin mRNA was used as a template for reverse transcription[23]. The cDNA obtained was converted into double-stranded S_1 nuclease-resistant DNA[23]. Double-stranded cDNA of 1.2–1.7 kilobases was eluted from a 3.5% acrylamide gel and inserted into the *Pst*I site of pBR322 by the oligo(d(CG)) tailing method[23]. Host bacteria were transformed and colonies were screened by hybridization with the nick-translated cDNA insert of pRn5.3 as a probe. The recombinant plasmid containing the largest 5′ portion of renin message was chosen for further analysis and designated pRn4.7. For sequencing experiments, sites of endonuclease cleavage are indicated at the top. As shown by the *Pvu*I site position of the pBR322 plasmid, the recombinant plasmids pRn5.3 and pRn4.7 are inserted in inverse orientation at the *Pst*I site of vector DNA. DNA fragments were labelled either at the 5′ end (———) or at the 3′ end (– – –). Arrows indicate the direction and extent of nucleotide reading. *b*, Nucleotide sequence of mouse submaxillary renin cDNA as deduced from the sequence of plasmids pRn5.3 and pRn4.7. The amino acid sequence is that predicted from the nucleotide sequence.

Fig. 2 Comparison of mouse submaxillary renin and acid proteases primary sequences. The upper line gives the predicted amino acid sequence of renin, the four lower lines give the amino acid sequences of bovine and porcine pepsinogens, bovine prochymosin and penicillopepsin from *P. janthinellum*. Data are from Dayhoff[24]. Only the amino acids which differ from the renin chain are shown. Homologous positions are indicated by dashes. Deletions are indicated by parentheses. The single code for amino acids is given in ref. 24.

Fig. 3 Amino-terminal sequence analysis of renin A and B chains; 30 nmol each of chain A and chain B were analysed by automated Edman degradation in a Beckman sequencer 890C exactly as described elsewhere[25].

the formation of prorenin. The prorenin is converted into active mature renin by two proteic cleavages, each occurring after two basic residues: Lys 62–Arg 63 and Arg 352–Arg 353. The exact length of the A and B chains is not known because the carboxyl terminus of the two chains has not been determined. However, the molecular weight of the A chain as determined by SDS-gel electrophoresis (35,000) is close to that calculated from the deduced amino acid sequence (31,347). The addition to A and B chain (5,379) M_r gives a M_r of 36,698, close to that found by SDS-gel electrophoresis and equilibrium sedimentation, making extensive processing of the C-terminus unlikely.

Our model is based on the presence of a disulphide bond between the A and B chains. Cys 4 present in the B chain (Cys 357) is probably linked to Cys 320 of the A chain, by analogy with pepsin. Similarly, because the position of the cysteines is conserved in the acid protease family, it is likely that there is a disulphide bond between Cys 114 and Cys 121, and between Cys 277 and Cys 281.

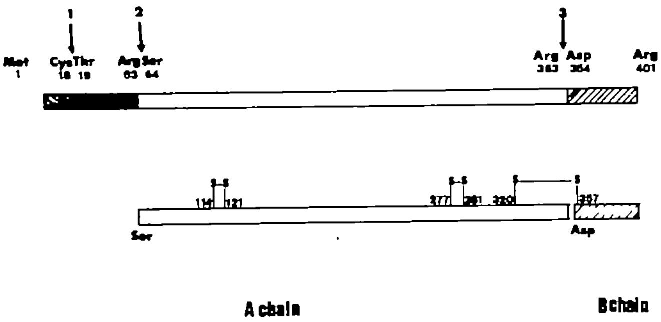

Fig. 4 A schematic representation of the possible maturation process of submaxillary gland renin. The model involves three cleavages: (1) removal of the peptide signal by membrane processing enzymes; (2), (3), conversion of the prorenin obtained into active mature renin by two cleavages occurring after a dibasic peptide and giving rise to the A and B renin chains linked by a disulphide bond.

Comparison of this model with the primary structures of carboxyl proteases and the mature form of these enzymes reveals interesting features: murine submaxillary renin and porcine cathepsin D[20] possess two chains; in the case of renin the processing of these two chains occurs after a dibasic peptide. This activation cleavage is distinctly different from the intramolecular activation mechanism of pepsinogen[21] but similar to that for proinsulin and other endocrine peptides[22]. It is not known whether submaxillary gland and kidney renins are identically processed from the same precursor molecule.

We thank J. L. Sikorav, P. Paraitaud and M. Cauvereys for help in DNA and protein sequence determinations, respectively, and H. Bedouelle for stimulating discussions. This work was supported by grants from the CNRS (ATP 4247), the Institut National de la Santé et de la Recherche Médicale (PRC 124024) and the Fondation pour la Recherche Médicale Française.

Prostatic steroid binding protein: gene duplication and steroid binding

Malcolm Parker, Maurice Needham & Roger White

Imperial Cancer Research Fund, PO Box 123, Lincoln's Inn Fields, London WC2A 3PX, UK

The principal secretory protein in rat prostatic fluid is a steroid binding protein[1–6] whose expression is stimulated by androgenic steroids[7,8]. This prostatic steroid binding protein is oligomeric, consisting of two subunits, one containing the polypeptides C1 and C3 and the other containing C2 and C3[9]. We have isolated cDNA clones specific for each of the mRNAs which code for prostatic binding protein and note here the considerable DNA sequence homology between C1 and C2. Therefore, it is likely that duplication of an ancestral gene occurred and the subsequent divergence results in the expression of two related polypeptides that form part of a single protein. Furthermore, in view of the structure of the protein it is possible that the divergence of one of the genes has resulted in the capacity of this prostatic protein to bind steroids.

Prostatic steroid binding protein is an oligomer consisting of two subunits[9]. In one subunit C3, a polypeptide of molecular weight (M_r) 12,000 is linked by disulphide bridges to C2, a polypeptide of M_r 10,000 and in the other subunit C3 is linked by disulphide bridges to C1, a polypeptide of M_r 8,000. These three polypeptides are encoded by discrete mRNAs and we have previously isolated cDNA clones for C1 and C3 mRNA[10] by using the ability of single-stranded cDNA to form a hairpin at its 3′ end in order to prime the synthesis of the second DNA strand[11]. As the cDNA inserts were much smaller than the estimated mRNA sizes, we have now used an alternative procedure which reduced the loss of DNA corresponding to the 5′ end of the mRNA[12,13]. Single-stranded cDNA was tailed with dCMP and synthesis of the second strand was primed with oligo(dG), thereby avoiding the use of S_1 nuclease which necessarily results in loss of DNA. After a second tailing reaction, dC-tailed double-stranded cDNA was inserted into the *Pst*I site of pAT153[14], which had been tailed with dGMP.

Transformants that contained the desired cDNA sequences were identified by *in situ* hybridization[15] using ^{32}P-labelled

Table 1 Relationships of prostatic binding proteins, mRNA and cDNA clones

Prostatic binding protein	Primary translation product	mRNA size (nucleotides)	cDNA plasmid	cDNA insert size (nucleotides)
8,000 (C1)	9,000	500–550	pA13	500
10,000 (C2)	11,000	550–600	pB44	500
12,000 (C3)	10,000	650–700	pA34	600

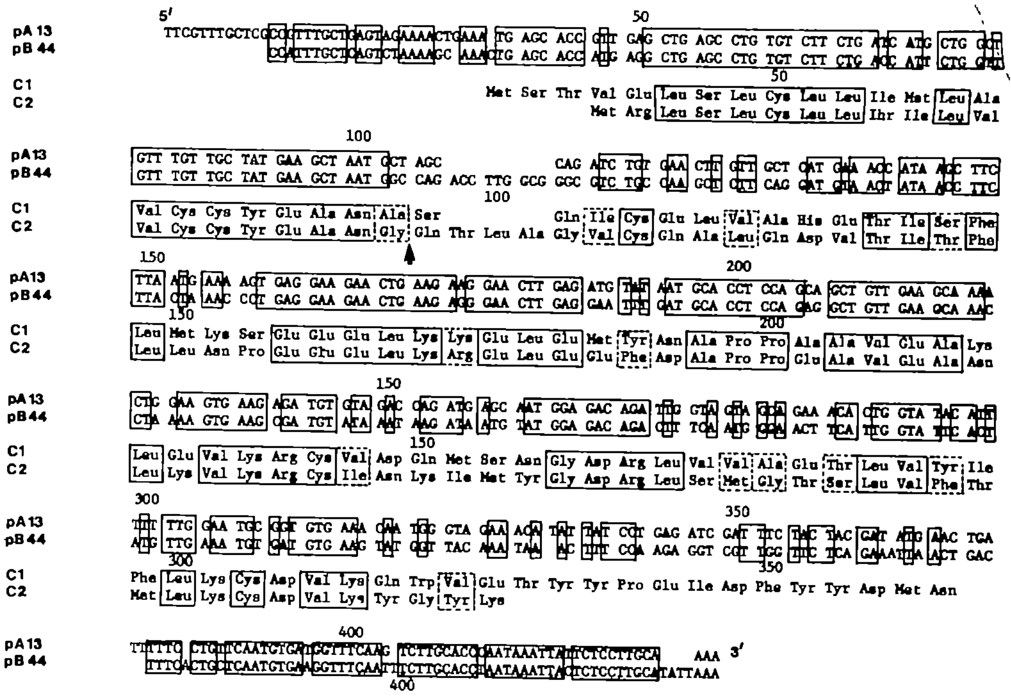

Fig. 1 Nucleotide sequence of prostatic binding protein mRNAs for C1 and C2 and deduced amino acid sequence The nucleotide numbers are shown above the sequence Gaps have been left to maximize homology; the solid boxes show perfect homologies and the dotted boxes show semi-conservative amino acid homologies The putative cleavage point of the signal peptide is represented by ↑. The cDNA clones pA13 and pB44 which were used to analyse the sequences of C1 and C2 were isolated as follows. Poly(A)-containing RNA was isolated from rat ventral prostate and used to synthesize prostate cDNA[8]. The cDNA was 'tailed' using terminal transferase with dCTP in the presence of 1 mM CoCl to yield molecules with ~20 dC at their 3′ ends[10]. After phenol extraction the tailed DNA was passed through a Sephadex G-150 column and annealed with oligo(dG) to prime the synthesis of the second DNA strand using reverse transcriptase[13] After phenol extraction and gel filtration the double-stranded cDNA was tailed again with dCTP using terminal transferase. pAT153[14] was digested with *Pst*I and tailed with ~20 dGMP molecules. Annealing of pAT153 and double-stranded DNA was carried out at a molar ratio of 1.1 by heating the mix at 60 °C for 2 h and cooling overnight. After transformation of *Escherichia coli* HB101 had been carried out, recombinant colonies were selected for tetracycline resistance. Further screening to distinguish colonies which contained the desired prostatic DNA sequences was carried out by *in situ* hybridization using ^{32}P-labelled cDNA[15] Plasmid DNA was isolated from transformed *E coli* by lysis with lysozyme and subsequent SDS treatment in alkaline conditions[34]. After purification on CsCl gradients the DNA was bound to diazobenzyloxymethyl paper as described previously[16] except that 25 μM sodium phosphate *p*H 6.5 was used in place of borate as buffer. The recombinant plasmid clones were then identified by mRNA purification. Total prostate poly(A)-containing RNA (6 μg) was hybridized to the filters, washed and the bound RNA eluted and translated in a cell-free system derived from wheat germ[35]. End-labelling of DNA with [γ-^{32}P]ATP and DNA sequence analysis were carried out using the methods of Maxam and Gilbert[19] The sequencing strategy was to 5′-end label pA13 that had been digested with *Bgl*II and *Hin*dIII and pB44 that had been digested with *Hin*f and *Hpa*II using [γ-^{32}P]ATP and T4 polynucleotide kinase.

cDNA. This was possible because the amount of hybridization with recombinant plasmids depends on the abundance of the individual cDNA species and the cDNAs that correspond to prostatic steroid binding protein mRNA represent by far the most abundant cDNA in the total mix. Individual recombinant plasmids were distinguished by mRNA purification[10,16]. Thus cDNA clones pA13, pB44 and pA34 (Table 1), which are specific for C1, C2 and C3, respectively, were selected for further studies. It was likely that they represented complete copies of the mRNAs because we and others[10,17,18] have estimated that the size of prostatic binding protein mRNAs, including the poly(A)-tail, was 450–700 nucleotides and the DNA insert sizes were consistent with the size of each corresponding mRNA (Table 1). Furthermore, preliminary mapping of mRNA transcripts synthesized *in vivo* indicates that the cDNA inserts extended to within 10 nucleotides of the 5′ ends of the mRNAs.

We sequenced the cDNA inserts[19] and found marked similarities between pA13 and pB44, resulting in extensive amino acid sequence homologies between C1 and C2 (Fig. 1). In contrast, the DNA sequence of pA34, which was consistent with the published protein sequence of C3[20], shows no significant homology with pA13 or pB44.

Both C1 and C2 mRNAs contain approximately 430 nucleotides. C1 mRNA contains: (i) A 5′ non-coding region of at least 36 nucleotides. (ii) A coding region of 333 nucleotides of which 264 correspond precisely to the secreted polypeptide of 88 amino acids[21]. In fact, there are two potential AUG initiation codons which could represent the NH$_2$ terminus of the protein. As these would result in signal peptides of 12 or 23 amino acids, we favour initiation of translation at nucleotide 37 because all signal peptides described so far contain 15–30 amino acids[22] and, in general, the first AUG initiation codon is utilized. (iii) A 3′ non-coding region of 60 nucleotides, including a UGA termination codon and a AAUAAA poly(A) addition signal 19 nucleotides preceding the poly(A)-tail. The C2 mRNA contains: (i) A 5′ non-coding region of 34 nucleotides. (ii) A postulated coding region of 294 nucleotides of which 60 probably comprise a signal peptides and 234 code for the secreted polypeptide, in agreement with the partial protein sequence which has been determined to date (B. Peeters and W. Rombauts, personal communication). This would be consistent with the sizes of the primary translation product synthesized *in vitro* and the processed polypeptide secreted *in vivo*[8]. In addition, we suggest that the signal peptide is cleaved at Asn-Gly-↑Gln which is used commonly by signal peptidases[22]. (iii) A 3′ noncoding region of 105 nucleotides which contains a UAA termination codon and a AAUAAA poly(A) addition signal 24 nucleotides preceding the poly(A)-tail.

The most remarkable feature of the two mRNAs, however, is the extent of sequence homology which occurs in both coding and non-coding regions and which results in a 50% amino acid sequence homology between the primary translation products and increases to 62% when semi-conservative amino acids are included (Fig. 1). The most striking homologies are shown in Fig. 2 and encompass: (i) the 5′ non-coding region of nucleotides 1–19 in pB44 and 13–31 in pA13 which share 79% homology, (ii) the signal peptide of nucleotides 22–99 in pB44 and 35–109 in pA13 which share 87% homology, (iii) the coding region of nucleotides 128–267 in pB44 and 131–269 in pA13 which share 76% homology and (iv) the 3′ non-coding region of

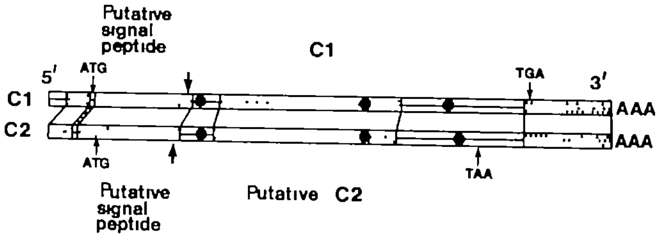

Fig. 2 Schematic representation of the major homologies between C1 and C2 mRNA. Hatched areas show regions of at least 75% DNA sequence homology. Possible homologous regions of less than 15 nucleotides have been omitted. The initiation codons ATG and termination codons TGA and TAA are shown by arrows and the putative signal peptides are shown preceding the arrows ↑ at which a signal peptidase may cleave. Cysteine residues (●) attach C1 and C2 to C3 by disulphide bridges.

nucleotides 362–432 in pB44 and 363–431 pA13 which share 81% homology. Several additional homologous regions of 15–20 nucleotides also exist but have been omitted for reasons of clarity.

The similarity in the DNA sequences in pA13 and pB44 suggest that the genes coding for C1 and C2 have probably arisen by duplication of an ancestral gene. There are now many examples of duplicated genes: some are pseudogenes[23–25], some are expressed at quite different levels with distinct control signals[26–28], and others are expressed in similar amounts[29,30]. C1 and C2 seem to fall into this last class, being similarly expressed and controlled by androgens in the rat ventral prostate and ultimately both forming part of a secreted steroid binding protein. It is also of interest that in blotting experiments[31] with rat and mouse DNA samples we find that pB44, but not pA13, hybridizes (at low as well as high stringency) with mouse DNA; therefore, we presume that gene duplication in the rat occurred after the evolutionary divergence of rat and mouse.

The divergence between the C1 and C2 genes may be of functional significance in view of the structure of prostate binding protein[9] and its steroid binding properties[2,6,32]. After dissociation of the protein into the two subunits, only C2–C3 continue to show steroid binding[9]. Although this experiment is open to several interpretations, the only apparent difference between the subunits is the composition of C1 and C2 and therefore one intriguing possibility is that a portion of C2 is crucial for steroid binding. In spite of this, it is extremely difficult to predict which regions of C2 are important because amino acid differences, which could markedly affect the conformation of the protein, occur throughout the two polypeptides. Moreover, it is conceivable that C2 does not bind steroids directly but may interact with C3 in such a way as to enable the C2–C3 subunit to bind steroids. Nevertheless, as estramustine, a nitrogen mustard derivative of oestradiol-17β, binds with a K_d of 2×10^{-8} M[32] and has been used as a therapeutic agent in the treatment of prostatic carcinoma[33], it will be of considerable interest to investigate whether similar genes can be detected in human DNA.

Inverted repeats surround the ribitol–arabitol genes of *E. coli* C

Christopher D. Link* & Albey M. Reiner

Department of Microbiology, University of Massachusetts, Amherst, Massachusetts, 01003, USA

Only 10–20% of natural *Escherichia coli* strains can catabolize the pentitol sugars ribitol and D-arabitol[1]. This variability extends to common laboratory strains: *E. coli* C strains, but neither K12 nor B strains, can catabolize these sugars. In *E. coli* C, the genes responsible for these catabolic pathways are chromosomal and consist of two very closely linked, independent operons[2]. Genetic[1] and hybridization studies (C.D.L. and A.M.R., unpublished data) indicate that the genes are completely absent in K12. These observations led us to consider whether these genes had been acquired by horizontal, rather than vertical, genetic transmission, perhaps as an inserted transposable element. Here we report that the ribitol-arabitol genes of *E. coli* C are surrounded by 1.4 kilobase (kb) inverted repeats of imperfect homology. These genes may constitute an example of a vestigial transposable element recently acquired by the bacterial chromosome.

To examine the physical structure of the ribitol–arabitol chromosomal region, the ribitol–arabitol genes of *E. coli* C were cloned *in vivo* on a λ specialized-transducing phage (designated λdAR) and *in vitro* by recombinant DNA techniques. Preliminary electron microscopy with DNA from λdAR suggested that this phage contained inverted repeats, structures often associated with transposable elements[3,4]. To investigate this possibility further, single strands of λdAR and of two λ control phages were separated and purified by the poly(U, G)/CsCl equilibrium gradient method[5]. Renaturation of single-stranded phage DNA in the absence of its complementary strand yields duplex regions only by formation of intrastrand duplexes resulting from inverted repeat sequences in the original double-stranded molecule. These intrastrand duplex regions can be visualized and sized by degrading the unpaired single-stranded DNA with nuclease S_1 and displaying the remaining duplex DNA by gel electrophoresis[6].

The gel banding pattern produced when single-stranded DNA from λdAR and control phage λY199::*tn10* (which contains transposon Tn*10*) is treated with S_1 nuclease is shown in Fig. 1. Single-stranded λdAR DNA produces multiple bands with a major band having the mobility of an ~1.4 kb fragment, and minor bands running at ~0.7 and 0.6 kb (Fig. 1, lanes *f–i*). These bands are never observed with single-stranded DNA from Y199, the parent phage of λdAR. In contrast, DNA from phage λY199::Tn*10* produces a single sharp band (Fig. 1, lanes *b–e*) corresponding to 1.36 kb, which is the size of the Tn*10* inverted repeats as estimated by electron microscopy[7]. These results demonstrate that λdAR, like λY199::Tn*10*, contains inverted repeats. The multiple banding pattern of λdAR presumably reflects imperfect homology between two sequences of ~1.4 kb, resulting in single-strand 'bubbles' of non-homology in the intrastrand duplex which may be cleaved by S_1 nuclease. This view is supported by the observation that increasing the S_1 nuclease concentration shifts the banding pattern of λdAR towards smaller, more numerous fragments (Fig. 1), and by hybridization experiments described below.

To locate these imperfect repeats with respect to the ribitol–arabitol genes, and to exclude the possibility that the inverted repeats found on the λdAR genome are an artefact generated during *in vivo* formation of this phage, we also worked with the genes cloned by recombinant DNA techniques. Cloning was achieved by randomly ligating *Eco*RI fragments of *E. coli* C chromosomal DNA into the plasmid vector pBR322. (*Eco*RI was chosen after preliminary experiments demonstrated that an *Eco*RI fragment of λdAR includes both the ribitol–arabitol

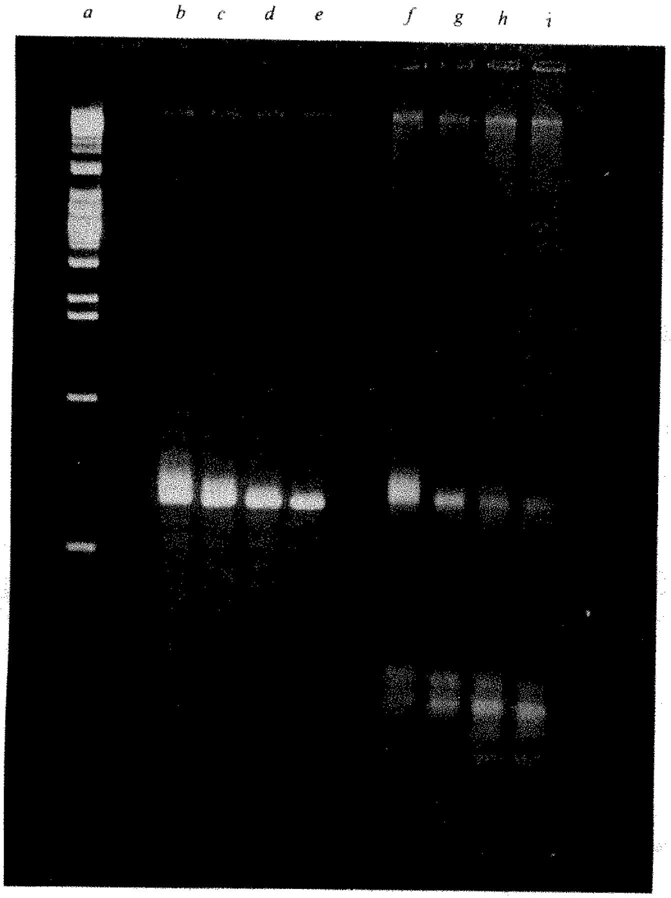

Fig. 1 Gel electrophoresis of intrastrand duplex fragments which survive S_1 nuclease digestion of renatured single-stranded DNA from λY199::Tn*10* (lanes *b–e*) and λdAR (*f–i*). Phage λY199::Tn*10*, used as a control, was constructed by selecting a recombinant between λY199 and the Tn*10*-containing phage λ561[18]. Preparations of separated strands of phage DNA were renatured by heating for 1 h in 0.3 M NaCl at 65 °C. S_1 nuclease digestions were done as described earlier[6] and the digested samples were run on a 1.4% agarose gel. Lane *a* contains an *Eco*RI-*Bam*HI double digest of λ^+ and pBR322 as a size standard. Lanes *b–e* contain 1.4 μg of λY199::Tn*10* DNA, *f–i* contain 3.2 μg of λdAR DNA. The digestions were done using 20 (*b, f*), 40 (*c, g*), 80 (*d, h*) or 120 (*e, i*) units of S_1.

genes and the inverted repeats.) All transformants selected for their ability to use ribitol or D-arabitol could utilize both sugars, and all examined further harboured a plasmid in which a large (16.5 kb) *Eco*RI fragment had been inserted into pBR322. One of these plasmids, designated pAR-2, was chosen for further restriction mapping.

The relative locations of the inverted repeat sequences were determined by preparing Southern transfers of restriction enzyme digests of pAR-2 and probing with ^{32}P-labelled inverted-repeat DNA. The probe was prepared by first extracting from an agarose gel the major intrastrand duplex fragment which survives S_1 nuclease treatment of λdAR (Fig. 1) and then labelling the fragment *in vitro* by nick translation[8]. Lane *a* of Fig. 2 is a positive control showing hybridization of the probe to the intrastrand duplex fragments produced by S_1 treatment of λdAR. (The hybridization of the probe to the minor bands demonstrates that the smaller fragments are derived from the major intrastrand duplex fragment.) The hybridization patterns of the pAR-2 digests (Fig. 2*b–e*) were used to locate the inverted repeats relative to previously mapped restriction fragments of this plasmid. The repeats were found to lie in two noncontiguous fragments separated by 7.2 kb (see Fig. 3).

Similar hybridization studies show that the inverted repeat probe does not hybridize to Tn*5*, Tn*10*, or *E. coli* K12 chromosomal DNA, even in conditions that would detect partially homologous sequences[9]. Hybridization of the probe to *E. coli* C chromosomal DNA was limited to fragments present in pAR-2, demonstrating that the only copies of the repeat unit in the *E. coli* C chromosome are those surrounding the ribitol–arabitol genes.

The location of the individual genes of the ribitol and D-arabitol operons relative to the inverted repeats was determined by experiments with pAR-2 plasmids into which the kanomycin-resistance transposon Tn*5* had been inserted[10]. Inserts which prevented either ribitol or D-arabitol use were mapped by restriction enzyme analysis, and the individual genes inactivated were determined by genetic complimentation. The gene order determined in this manner was in complete agreement with the order previously determined by standard genetic methods[2]. The repeats bound the ribitol–arabitol genes in a transposon-like arrangement (Fig. 3). Although these experiments do not exclude the possibility that distal portions of the ribitol or D-arabitol genes contribute to the repeated sequences, results with the ribitol–arabitol region of the related bacteria *Klebsiella* have shown that no detectable hybridization exists between these operons, although hybridizing fragments were detected outside the operons[11].

As the repeat sequences surrounding the ribitol–arabitol genes are not found elsewhere in the *E. coli* C chromosome, or anywhere in the *E. coli* K12 chromosome, it is unlikely that they represent insertion sequences which coincidentally surround the ribitol–arabitol genes. The inverted repeats could result from residual homology retained from an ancestral tandem inverted duplication[12]; this is improbable, however, in light of the non-homology of the ribitol and D-arabitol operons. We

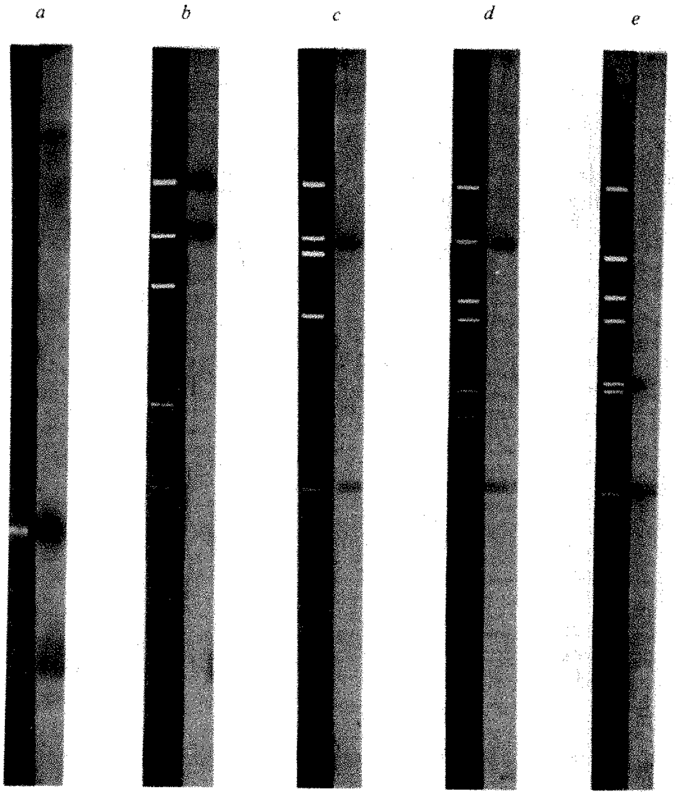

Fig. 2 Hybridization of the ribitol–arabitol inverted repeat probe to digests of pAR-2. The probe was created by electroeluting from an agarose gel the major intrastrand duplex fragment of λdAR (see Fig. 1) and then labelling this fragment with ^{32}P by nick translation[8]. Restriction fragments of pAR-2 and pAR-2 derivatives were fractionated on a 1% agarose gel and transferred to nitrocellulose by the method of Southern[19]. Pretreatment of nitrocellulose filters and hybridization incubations were done as described previously[20]. The probe was hybridized to: *a*, intrastrand duplex fragments generated by S_1 nuclease digestion of λdAR single-stranded DNA; *b*, *Eco*RI–*Bam*HI–*Hin*dIII triple digest of pAR-2; *c*, *Pst*I digest of pAR-2; *d*, *Pst*I digest of pAR-2 containing a Tn*5* insert in the gene for D-xylulose kinase; *e*, *Pst*I digest of pAR-2 containing a Tn*5* insert in the gene for D-ribulose kinase.

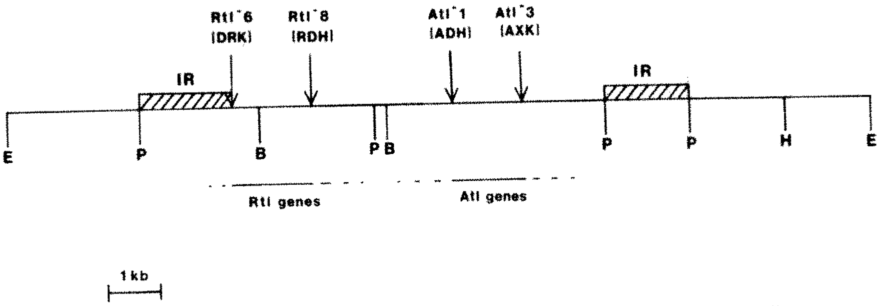

Fig. 3 Map of the 16.5 kb *Eco*RI fragment cloned in pAR-2. Hatched regions indicate fragments which hybridize to the inverted repeat (IR) probe. Arrows indicate location of representative TN*5* insertions which inactivate ribitol or D-arabitol genes. Tn*5* insertions were generated by delivering the Tn*5* element via defective λ phage[10] to strain AB1157 containing pAR-2. The subpopulation of pAR-2 plasmids which received Tn*5* inserts was enriched by preparing plasmid DNA from all transposon-receiving cells, then using this to transform another strain to kanamycin resistance. Those inserts in pAR-2 were identified by screening the kanamycin-resistant transformants for inability to use ribitol of D-arabitol. Complementation studies were done by transforming a strain containing active ribitol and D-arabitol dehydrogenases, but inactive D-ribulose and D-xylulose kinases, with insert-containing plasmids. Because of the polarity of Tn*5* insertions, this complementation test cannot distinguish between dehydrogenase and promoter insertions. Letters in parentheses indicate enzyme coded for by inactivated gene: DRK, D-ribulose kinase; RDH, ribitol dehydrogenase; ADH, D-arabitol dehydrogenase; AXK, arabitol-induced D-xylolose kinase. The maximum rightward extent of the left IR region was determined by experiments with pAR-2 containing Tn*5* insertion Rtl$^-$ 6, which show that only the left-hand plasmid–Tn*5* junction fragment hybridizes to the probe (see Fig. 2, lane *e*). Restriction sites for *Sal*I, *Hpa*I and *Bgl*II were omitted for clarity. B, *Bam*HI; E, *Eco*RI; H, *Hind*III: P, *Pst*I.

suggest that the inverted repeats are the structural remnants of an ancestral transposable element which carried the ribitol–arabitol genes into *E. coli*. This would account for the observation that only a subpopulation of *E. coli* strains can use ribitol and D-arabitol.

The imperfect homology of the inverted repeats suggests that they no longer function in transposition. Conjugation experiments (not shown) which demonstrate that the ribitol–arabitol genes do not seem to translocate from the chromosome ($<10^{-9}$ transpositions per gene copy) support this view. The hypothesis that the inverted repeats are derived from a transposable element could be further supported by demonstrating that the repeats themselves are flanked by short inverted repeats, or that the ends of the presumptive ribitol–arabitol transposon are flanked by a duplication of an oligonucleotide of target DNA. However, these transposon characteristics[4] may be difficult to detect in this case because of the genetic drift which has apparently occurred since the insertion of these genes.

If the *E. coli* ribitol–arabitol region did originate as a transposon, then these genes can be viewed as a rare example of genes for which there is a molecular record of their acquisition by a bacterial chromosome[13]. What other chromosomal genes might have been derived from transposable elements? As transposons seem to carry genes of potentially strong selective advantage, chromosomal genes conferring catabolic traits or resistance to toxic agents could be derived from transposable elements. For example, certain chromosomal genes which confer antibiotic resistance (such as *ampC* of *E. coli*[14]) might also be found to be surrounded by inverted repeats. The *E. coli* genes for restriction and modification (*hsd*), which are nonessential and can convey potentially strong selective advantage, may also be candidates for genes derived from transposons. (Restriction and modification genes have not yet been identified as part of transposable elements, although they can be phage or plasmid borne[15].) Some of the inverted repeat sequences detected in the *E. coli* chromosome by electron microscopy[16,17] may be evidence of past transposon insertions. The fraction of chromosomal genes derived from transposons may be significantly greater than the fraction of genes eventually found associated with inverted repeats, as one would expect the identifying structural features of genes derived from transposons to be lost with time.

Treatment of *Escherichia coli* with radiation or chemical carcinogens induces a number of cellular functions to counteract the damage inflicted by such treatments (see ref. 1 for a review). One of these inducible functions is the SOS response, which is controlled by the *recA* and *lexA* genes: single-stranded DNA produced as a result of DNA damage binds to *recA* protein (RecA), activating its protease function; activated RecA cuts *lexA* protein (LexA), the repressor of the SOS genes, thereby inactivating it and turning on these genes[2–4]. The SOS genes include *recA* and *lexA* themselves, and recent work has shown that the two genes have similar operators where LexA binds *in vitro*, inhibiting their transcription[3,4]. It is anticipated that other genes under the control of *recA* and *lexA* will have similar operators. Recent genetic[5,6] and biochemical[7] data suggest that the excision repair genes *uvrA* and *uvrB* are part of the *recA–lexA* regulon and are at least partly responsible for *recA–lexA*-mediated inducible DNA repair. In support of these results we have reported that *uvrB* has a promoter that is repressed by LexA *in vitro*[8]. We now show that *uvrA* has an operator similar to those of other SOS genes and that LexA binds to this operator and inhibits the transcription of the *uvrA* gene *in vitro*.

---

[*] To whom correspondence should be addressed.

To study the regulation of *uvrA* we used the plasmid pDR1996 (see Fig. 1*a*) which carries both the *uvrA* and *ssb* genes[9]. The exact location of *ssb* on this plasmid was determined from DNA and protein sequencing[9]. The direction of transcription of *uvrA* and the approximate location of its promoter were determined by Tn*1000* mapping[10]. The exact location of the *uvrA* promoter was determined by subcloning and transcription experiments: removal of the *Bal*I–*Kpn*I fragment spanning 6.7–7.5 kilobases (kb) inactivated *uvrA* while transcriptional experiments indicated a single transcriptional start between the *Hae*III site at 6.73 kb and the *Hin*fI site at 7.03 kb (data not shown). This transcript was presumed to be that of *uvrA*, and this $(HaeIII\text{-}HinfI)_{325}$ fragment was sequenced to obtain the nucleotide sequence of the *uvrA* promoter shown in Fig. 1*b*. The transcriptional start point in this sequence was determined from RNA sequencing of the [γ-^{32}P]-labelled transcript made *in vitro* (data not shown) and is indicated as +1 in the figure.

To study the effect of LexA on *uvrA* transcription, LexA was included in the *in vitro* transcription reactions. As seen in Fig. 2, when present at concentrations similar to those used for *recA* and *lexA*[2], LexA markedly inhibits transcription of the *uvrA* gene. This inhibition is the result of specific binding of LexA to the promoter–operator region of *uvrA*, as is demonstrated by the DNase I protection experiments ('footprinting', see Fig. 3). As seen in Fig. 3, LexA protects from DNase I digestion a 25–30-base pair (bp) segment that overlaps the *uvrA* promoter.

Fig. 1 *a*, Restriction map of the *uvrA* plasmid, pDR1996. The vector (pBR322) sequences are shaded. The locations and directions of transcription of *uvrA* and *ssb* are indicated by the heavy arrows on the map. The region whose sequence is shown in *b* is indicated by a bar beneath the detailed restriction map of the 0.6-kb *Ava*II fragment carrying the *uvrA* and *ssb* promoters. *b*, Sequence of the promoter–operator regions of *uvrA* and *ssb*. The −35 sequence and Pribnow box for *uvrA* are boxed. The previously determined[9] initiation codon of *ssb* and the initiation codon for *uvrA* (unpublished data) are indicated by dashed boxes. The region protected from DNase I by LexA is bracketed; dashed lines at the ends of the brackets indicate regions of uncertainty as to the extent of LexA protection. Numbering is from the transcription start site of *uvrA* determined by RNA sequence analysis as previously described[8].

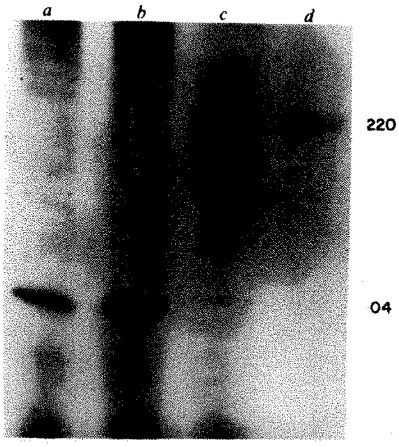

Fig. 2 Inhibition of *uvrA* transcription by LexA *in vitro*. pBR322 DNA and the $(HaeIII\text{-}HinfI)_{325}$ fragment of pDR1996 were transcribed *in vitro* in the presence and absence of LexA. Transcription reactions using 2.5 μg ml^{-1} of template and 14 μg ml^{-1} of LexA were performed as described previously[8] except that the transcription buffer contained 30 mM KCl. Transcripts were analysed on a 6% polyacrylamide gel containing 9 M urea and visualized by autoradiography. In lanes *a* and *b* 75% of the reaction mixture was loaded onto the gel while in lanes *c* and *d* 25% of the total reaction volume was loaded. The length of the transcript (shown in nucleotides at the right of the figure) was determined by comparison with ^{32}P-labelled ΦX174 DNA. The 104-nucleotide transcript from pBR322 (used here as a control) has been described previously by Levine and Rupp[13]. The 220 nucleotide-long transcript initiated from the *uvrA* promoter was found to consist of two discrete RNA species which differed in length by ~10 nucleotides but possessed the same sequence at their 5′ ends (data not shown). *a*, pBR322 minus LexA; *b*, pBR322 plus LexA; *c*, pDR1996 $(HaeIIIB\text{-}HinfI)_{325}$ minus LexA; *d*, pDR1996 $(HaeIIIB\text{-}HinfI)_{325}$ plus LexA.

Inspection of the protected region reveals that it has extensive sequence homology with the LexA binding sites found in the *recA*, *lexA* and *uvrB* genes[2,3,8] and the postulated LexA binding site in the colicin E1 gene, *cleI* (ref. 11). A comparison of these various operators is shown in Fig. 4, from which two conclusions can be reached. First, although all the operators have considerable sequence homology with the *recA* operator, which has a near-perfect dyad symmetry, the only conserved dyad symmetry is 5′CTG(N)$_{10}$CAG3′, suggesting that this structure might be an important feature of the LexA binding site. Second, the positioning of the LexA binding site relative to the two promoter defining sequences, the '−35 sequence' and the Pribnow box, varies in the different genes. Thus, the LexA binding site overlaps with the −35 sequence of *uvrA*, occupies the region extending from the −35 sequences to the Pribnow boxes of *recA* and *uvrB*, covers the Pribnow box and the transcriptional start site of *lexA* and occupies the region 3′ to the Pribnow box of *cleI*. These varied locations of the LexA binding site may provide flexibility for additional regulatory circuits for individual genes by leaving specific regions in the promoters accessible to regulatory factors other than LexA. In this regard, it is of interest that the *uvrA* and *uvrB* genes share a homologous sequence that is only partly included in the LexA binding site (see Fig. 4). This sequence may be the recognition site of a repressor specific for these genes. (Note that such a repressor would inhibit transcription from the first *uvrB* promoter, P1, which is not influenced by LexA *in vitro*[8].) Similarly, there is evidence that two other *recA*–*lexA*-controlled genes, *cleI* and *himA*, have second repressors in addition to LexA[11,12], and it is likely that the operators for these repressors do not or only partly overlap with the LexA binding site. The SOS response is a drastic reaction by the cell, causing a major perturbation in cell physiology and in some cases, even leading to cell death

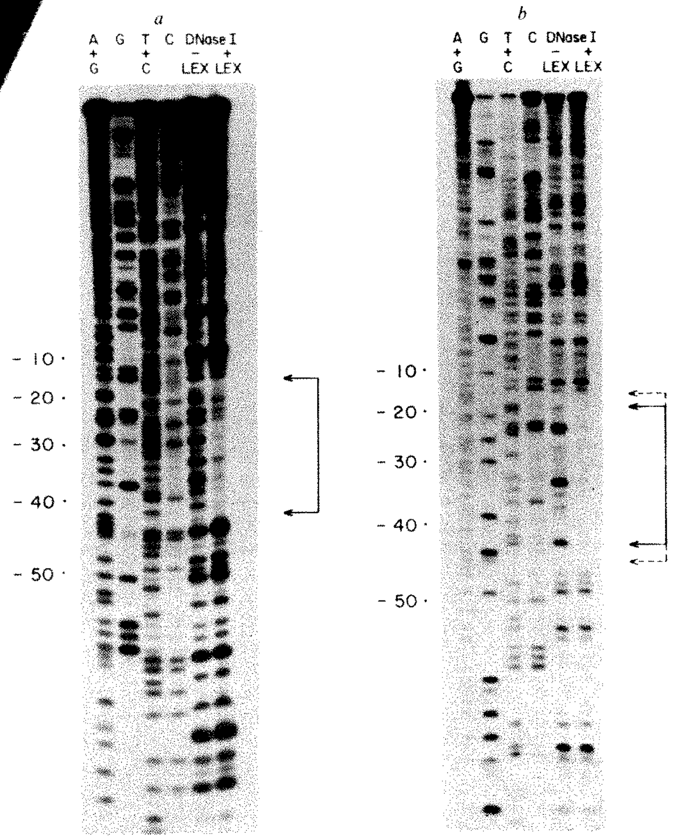

Fig. 3 Protection of the *uvrA* operator by LexA against digestion with DNase I (footprinting). The (*Hae*III–*Hin*fI)$_{325}$ fragment of pDR1996 was labelled with ^{32}P at the *Hae*III site at either the 5′ or 3′ end and then subjected to chemical sequencing[14] or DNase digestion[15] in the presence or absence of LexA. The conditions for footprinting were essentially as described before[4,8,15]. The bases are numbered relative to the start point of *uvrA* mRNA, which is designated +1. The protected regions are bracketed and the positions where the effect of LexA protection could not be determined due to lack of DNase I cleavage are indicated by broken lines. *a*, Top strand (5′ label); *b*, bottom strand (3′ label).

Fig. 4 Location of LexA binding sites in the promoter–operator regions of various genes that are controlled by *recA* and *lexA*. The 22-base pair dyad symmetry in the *recA* gene and the sequences in the other genes corresponding to this palindrome are in the dashed box. The −35 sequence of *cle1* (colicin E1) is not included for simplicity. Note that there are two tandem operators in *lexA*[3] and that the potential LexA binding site of *cle1* is included in a larger dyad symmetry[11]. *uvrB* has at least two transcriptional start sites, one marked +1 and the second at −31. Transcription from −31 but not from +1 is inhibited by LexA[8]. The regions of sequence homology between *uvrA* and *uvrB* are underlined. Other symbols are as in Fig. 1.

(as in the case of lambda induction). Thus, it may be advantageous for genes repressed by LexA to have additional regulatory controls that can function to fine-tune the response of different genes to different inducing stimuli, and perhaps also to cause expression of some SOS genes in conditions that do not lead to a full-scale SOS response.

The *uvrD* gene of *E. coli* encodes a DNA-dependent ATPase

Kenji Oeda, Takashi Horiuchi & Mutsuo Sekiguchi

Department of Biology, Faculty of Science, Kyushu University 33,
Fukuoka 812, Japan

Mutations in the *uvrD* gene of *Escherichia coli* K-12 result in multiple phenotypes, including increased sensitivity to UV light and ionizing radiation, decreased ability for host cell reactivation, increased spontaneous mutation frequency and decreased rate of genetic recombination[1–6]. It has been shown, moreover, that double mutants having mutations in both *uvrD* and *polA* genes are conditionally lethal[7–10]. The pleiotropic phenotypes of the *uvrD* mutants suggest that the *uvrD* gene product may have important roles in the processes of DNA repair, recombination and replication. To study the function of the *uvrD* gene, we have constructed hybrid phages and plasmids that carry the gene[11]. Here we have analysed the proteins synthesized by the hybrid phages and report that the *uvrD* gene product is a polypeptide of molecular weight (MW) 75,000. We present evidence that the *uvrD* protein possesses a DNA-dependent ATPase activity.

A hybrid phage, λ*uvrD*$^{+}$, which is able to complement *uvrD* mutations, was constructed using λgt·λc as cloning vector[11]. In addition to the *uvrD* gene, λ*uvrD*$^{+}$ carries the *corA* gene that controls transport of Mg^{2+}, Mn^{2+} and Co^{2+} through the cell membrane[12,13]. A hybrid phage, λ*corA*$^{+}$, which carries the *corA* gene alone, was also constructed[11]; this served as a control. We have isolated various deletion mutants from λ*uvrD*$^{+}$ using the method of Saito and Uchida[14]. Of these deletion mutants, Δ41 and Δ48 were able to complement *corA* but not *uvrD* mutations, while Δ49 was unable to complement either mutation.

λ*uvrD*$^{+}$ contains a 6.8-kilobase pair (kbp) DNA fragment derived from the *E. coli* chromosome and a part (4.0 kbp) of the γδ sequence (transposon Tn*1000*) derived from F plasmid[11]. DNA fragments generated from these phages using restriction endonucleases were analysed by agarose gel electrophoresis, and physical maps constructed (Fig. 1).

Proteins produced by the λ transducing phages were labelled with a ^{14}C-amino acid mixture and analysed by SDS-polyacrylamide gel electrophoresis (Fig. 2). Compared with cells infected with λgt·λc, two specific bands, corresponding to polypeptides

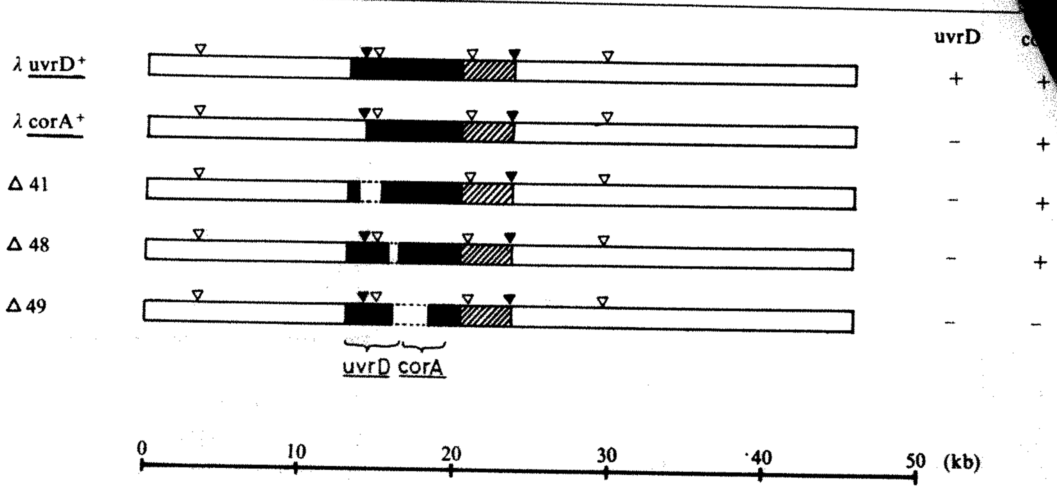

Fig. 1 Physical maps of transducing λ phages. Cleavage maps were constructed by digestion with restriction enzymes followed by agarose gel electrophoretic analysis as described previously[11]. Origins and restriction enzyme target sites are: ■, *E. coli* DNA; ▨, γδ sequence; □, λ phage DNA; [ ], deletion; ▽, *Bam*HI target sites; ▼, *Eco*RI target sites. Phenotypes of *uvrD3* or *corA5738* cells lysogenized with each transducing phage are shown on the right-hand side.

of molecular weight 75,000 and 37,000, were found in cells infected with λ*uvrD*⁺. The 75,000-MW polypeptide was identified as the *uvrD* gene product, because it was absent from cells infected with λ*corA*⁺, Δ41 or Δ48, which lack the intact *uvrD* gene. The 37,000-MW polypeptide seems to be the *corA* gene product; it is absent from Δ49.

Of the many proteins known to be involved in DNA metabolism, there are some whose molecular weight is ~75,000. These include DNA-dependent ATPase I[15,16] and DNA helicase II[17,18]. Recent studies suggested that they may be the same proteins[19]. Thus, we have examined DNA-dependent ATPase activity in cells infected with *uvrD*⁺ transducing phage. To overproduce the *uvrD* protein, the *susQ* mutation[20] was introduced into both λ*uvrD*⁺ and λ*corA*⁺ by recombination of each phage strain with λ*imm434 susQ21*. A culture of *E. coli* W3623 (*uvrD*⁺ *Su*⁻) infected with λ*uvrD*⁺ *susQ* was collected 195 min after infection, and an extract was subjected to DEAE-cellulose filtration, ammonium sulphate fractionation and phosphocellulose chromatography. As a control, an extract of λ*corA*⁺ *susQ*-infected cells was processed similarly.

Figure 3 shows elution profiles of DNA-dependent ATPase activity from phosphocellulose columns. Both samples showed activity eluting as a single peak at almost the same position as that reported for DNA-dependent ATPase I in these conditions[15]. The ATPase activity was totally dependent on denatured DNA and was sensitive to *N*-ethylmaleimide, as was observed with the enzyme from normal cells. We estimated that λ*uvrD*⁺-infected *uvrD*⁺ cells contain about 14 times more ATPase activity than λ*corA*⁺-infected *uvrD*⁺ cells. The small peaks in Fig. 3*b* may represent composites of ATPases, which were shown to be present in phosphocellulose eluates[21].

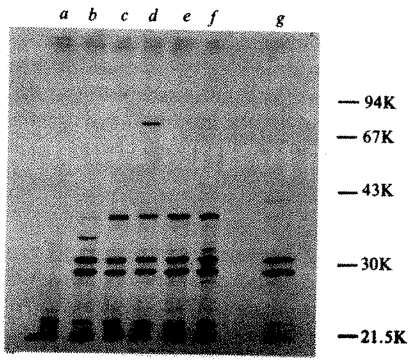

Fig. 2 Proteins produced by transducing λ phages. *E. coli* KY3304 lysogenic for λ*CI857* was grown in RM medium at 30 °C to a density of 2×10^8 cells ml^{-1} and infected with one of the transducing phages at a multiplicity of 10. The cells were labelled with ^{14}C-amino acid mixture at 30 °C for 50 min and extracts were prepared[28]. The polypeptides were analysed by electrophoresis on 10% SDS-polyacrylamide gels followed by fluorography, as described previously[29]. The positions of phosphorylase B [MW 94,000 (94K)], bovine serum albumin (67K), ovalbumin (43K), carbonic anhydrolase (30K) and soybean trypsin inhibitor (21.5K) are indicated. *a*, Uninfected; *b*, λgt·λc; *c*, λ*corA*⁺; *d*, λ*uvrD*⁺; *e*, Δ41; *f*, Δ48; g, Δ49.

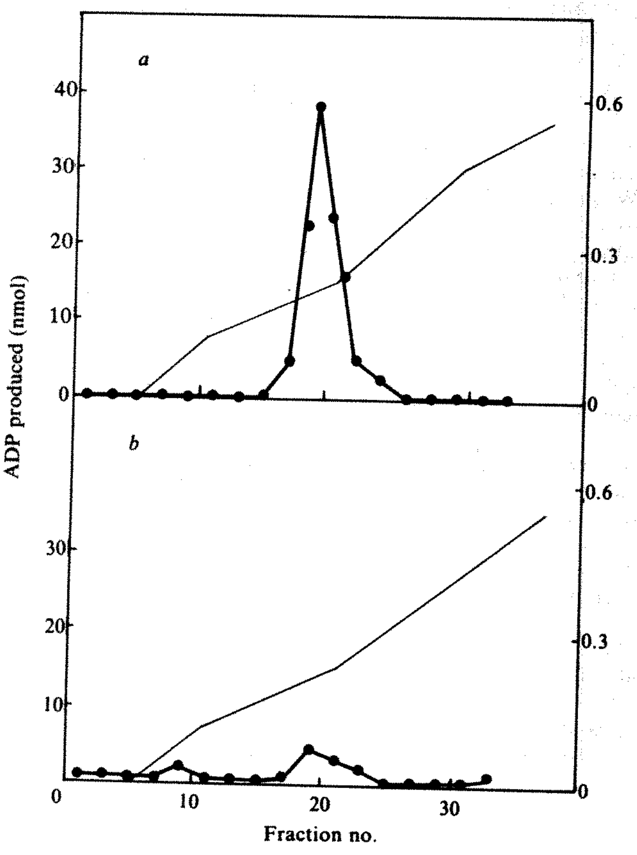

Fig. 3 Chromatographic resolution of DNA-dependent ATPase. *E. coli* strain W3623 (*uvrD*⁺ *Su*⁻) was infected with λ*uvrD*⁺ *susQ* (*a*) or λ*cor*⁺ *susQ* (*b*). The extracts were prepared from ~3 g of the infected cells and processed as described elsewhere[15]. Fraction II was applied to a phosphocellulose column (0.6×6 cm) and eluted with a linear gradient of 0.04–0.6 M NaCl in 0.02 M potassium phosphate buffer (*p*H 7.2). DNA-dependent ATPase activity was determined using 5 μl of each fraction. The reaction mixture (75 μl final volume) contained 50 mM Tris-HCl (*p*H 7.5), 20 mM 2-mercaptoethanol, 2 mM MgCl_2, 1 mM [γ-^{32}P]ATP (1×10^5 counts min^{-1}), 15 μg bovine serum albumin, and 7.5 nmol of heat-denatured calf thymus DNA. Incubation time, 20 min. A peak fraction (no. 19) of each sample was used for further analysis (see Fig. 4).

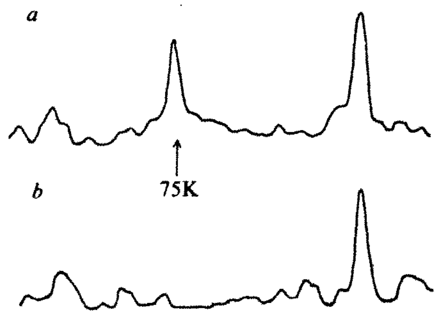

Fig. 4 Analysis of DNA-dependent ATPase fractions by SDS-polyacrylamide gel electrophoresis. Enzyme fractions (14 μl) from λ*uvrD*$^+$-infected (*a*) and λ*corA*$^+$-infected (*b*) cells were applied to 10% SDS-polyacrylamide gels and electrophoresed at 20 mA for 3 h. The gels were stained with Coomassie brilliant blue and scanned using a densitometer. Electrophoresis was from right to left. An arrow indicates the 75,000-MW polypeptide.

The enzyme fractions were further analysed by SDS-polyacrylamide gel electrophoresis. Figure 4 shows the patterns of proteins present in each of the peak fractions. In the λ*uvrD*$^+$ sample there was a large distinct band corresponding to the 75,000-MW protein whereas only a small band was observed at the corresponding position of the λ*corA*$^+$ sample, although the sizes of the other bands were almost the same for both samples. The ratio of the amounts of the 75,000-MW protein for the two samples was 12:1, very similar to that of the activities of the two samples.

These results suggest that the *uvrD* gene encodes a 75,000-MW protein which possesses a DNA-dependent ATPase activity. As this protein is similar in both size and chromatographic properties to DNA-dependent ATPase I[15,16], it is possible that the *uvrD* protein may be identical to DNA-dependent ATPase I. Recently, Richet *et al.*[19] isolated mutants that are defective in DNA-dependent ATPase I. Although they have correlated the mutations neither to certain phenotypes nor to a specific chromosomal locus, it is possible that the mutations might occur in the *uvrD* gene.

E. coli possesses several enzymes capable of unwinding DNA at the expense of ATP[17,18,21–27], and such enzymes may have vital roles in DNA replication, recombination and repair. Evidence has been presented that one of the enzymes, DNA helicase II, may be identical to DNA-dependent ATPase I[19]. Thus, it would be of interest to determine whether the *uvrD* protein possesses DNA unwinding activity. Studies on this are now in progress.

We thank Dr Yoshikazu Nakamura for sending us bacterial and bacteriophage strains and providing instruction in the method of protein labelling. This work was supported in part by Scientific and Cancer Research Grants from the Ministry of Education, Science and Culture of Japan.

A relationship between replicon size and supercoiled loop domains in the eukaryotic genome

Morphogénèse Animale, LA CNRS 179, UER Scientifique de
Luminy, F13288 Marseille Cedex 2, France

In interphase nuclei and metaphase chromosomes, eukaryotic chromosomal DNA is arranged in negatively supercoiled loops whose length averages several tens of kilobases (kb). Supercoiling indicates that the loops are tenaciously bound at both ends through the periodic attachment of DNA to a non-histone protein structural support, termed the nuclear matrix, skeleton or cage in interphase nuclei and the scaffold in metaphase chromosomes[1–16]. The looped organization has been envisaged to be important in DNA replication[2,11,15,17–25] and transcription[26–28]. We report here a close relationship between average loop length and replicon size in different animal and plant species. Autoradiographic experiments support the hypothesis that DNA synthesis occurs at fixed sites on the nuclear matrix[15,20]. We also describe a modification of the looped organization occurring during early embryonic development in *Xenopus laevis*.

We have investigated the supercoiled loop organization of erythrocytes (Fig. 1) and cultured cells (not shown) from *X. laevis* using the fluorescence halo technique[11]. Cells were treated with the non-ionic detergent NP40, dehistonized in 2 M NaCl containing various amounts of ethidium bromide or acridine orange and observed under the fluorescence microscope. The intercalation of either dye causes the dehistonized loops to form a DNase-sensitive and RNase-resistant fluorescence halo around the nuclear skeleton (Fig. 1*b*, *d*). The halo's radius (15 μm maximum) exhibits a characteristic 'breathing' in response to varying dye concentrations and prolonged UV irradiation (see Fig. 1 legend and refs 11, 23), thus supporting conclusions from different systems[11,23] that DNA is arranged in independent negatively supercoiled loops. Assuming that the largest fluorescence halo corresponds to completely unwound and extended DNA loops, then its radius gives a rough estimate of the average loop size (2 × 15 μm or ~90 kilobases in *X. laevis*).

We next investigated the relationship between the nuclear matrix, supercoiled loops and DNA replication in cultured *X. laevis* kidney cells using the fluorescence halo technique coupled with autoradiography. Asynchronous cells grown in monolayer on microscope slides were ^{3}H-thymidine-pulsed for 2 min. The cells were then treated *in situ* for maximal halo expansion and autoradiographed. After 2 min labelling, radioactivity covers almost exclusively the nuclear matrix (Fig. 2*a*).

0028–0836/82/260100–03$01.00

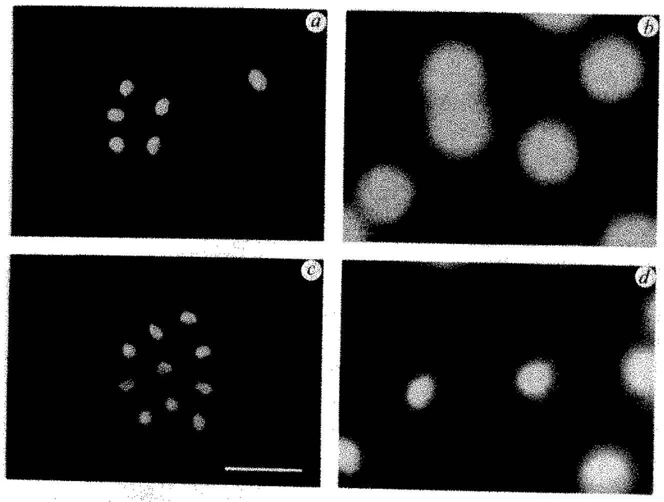

Fig. 1 Fluorescence micrograph of *X. laevis* erythrocyte nuclei. Freshly prepared blood smears were dipped for 30 s in ice-cold NP40 buffer (0.5% NP40, 10 mM MgCl, 0.5 mM $CaCl_2$, 1 mM phenylmethylsulphonyl fluoride, 50 mM Tris-HCl pH 7.5), stained with 5 μg ml^{-1} ethidium bromide (*a*) or 5 μg ml^{-1} acridine orange (*c*) and observed under the fluorescence microscope. When the dyes were dissolved in high-salt buffer (2 M NaCl, 0.2 mM MgCl, 10 mM Tris-HCl pH 7.5) at the same concentration a distinct fluorescence halo appeared (*b*, ethidium bromide; *d*, acridine orange). The halo radius (from the edge of the nuclear matrix to the edge of the halo) was measured using a micrometer eyepiece during the first few seconds following UV illumination. The radius reaches its maximum, ~15 μm, when the fluorochrome concentration is ~5 μg ml^{-1}; the lower or the higher the dye concentration, the smaller the halo (data not shown). However, at every dye concentration the maximal radius is attained following prolonged UV irradiation under the fluorescence microscope. These observations indicate that, with increasing dye concentrations, DNA loops are progressively unwound from a negatively supercoiled to a relaxed state and eventually forced into a positively supercoiled condition; whereas—independently from dye concentration—nicks introduced in the DNA by prolonged UV exposure remove the topological constraints thus lifting the maximal halo[11,23]. Scale bar, 45 μm.

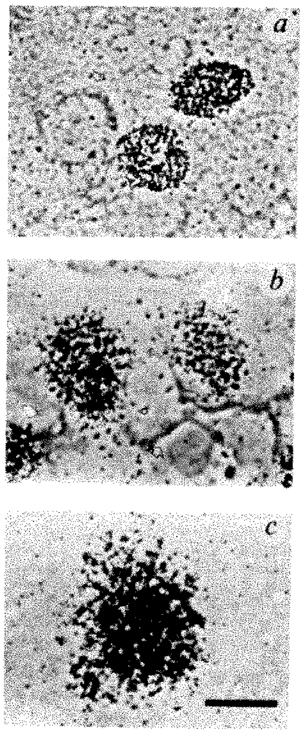

Fig. 2 Autoradioradiograms of *X. laevis* kidney culture cells pulsed with ^3H-thymidine and treated for maximal halo expansion. The fibroblast clone used stems from an established cell line (from Dr M. Cianfriglia, Siena). Cells were cultured in Eagle's minimal essential medium H_2O (100:40), supplemented with 10% fetal calf serum, at 26°C under 5% CO_2. Asynchronous cells growing in monolayer on microscope slides were pulsed with 20 μCi ml^{-1} ^3H-thymidine (42 Ci m-mol^{-1}; Amersham) for 2 (*a*), 10 (*b*), 30 (*c*) and 60 min or, in pulse-chase experiments (not shown), for 2 min followed by 0, 8, 28, 58 min chases with a 100-fold excess cold thymidine. The slides were then sequentially dipped in ice-cold distilled water for a few seconds, ice-cold NP40 buffer for ~30 s followed by 100 μg ml^{-1} ethidium bromide in high-salt buffer (see Fig. 1 legend) for ~1 min and exposed to a UV lamp (15 W, short wave) at a distance (~5 cm) and for a time sufficient for maximal halo expansion. After briefly rinsing with distilled water the slides were air dried and autoradiographed using Kodak NTB 2 undiluted autoradiographic emulsion. Exposure time was varied to obtain a roughly comparable grain density. Smoothed contours of several labelled areas, and of several unlabelled nuclear matrixes, were traced on enlarged prints of the autoradiograms, and assimilated to a circumference, using a Tektronix 4956 digitizer coupled to a 4051 desk top computer. Mean radius (in μm) of the labelled areas ±s.d. (number of measurements): 2 min pulse, 13.0 ± 0.85 (27); 10 min pulse, 17.2 ± 1.8 (30); 30 min pulse, 26.3 ± 1.9 (25); 60 min pulse, 27.6 ± 1.4 (29). Radius of the unlabelled nuclear matrix: 12.1 ± 0.9 μm (30). Average expansion rate of the labelled area: 0.47 μm min^{-1}. Arrows point to unlabelled nuclear matrixes. Scale bar, 25 μm.

Considering that the cells were in asynchronous growth active replicons were thus in all phases of replication, t observation suggests—in agreement with other investigation on different biological systems[2,11,18,20–23]—that in *X. laevis*, DNA synthesis occurs at fixed sites on the nuclear matrix. Nevertheless, the possibility that newly synthesized DNA binds nonspecifically to the nuclear matrix during extraction cannot be ruled out. Following 10 and 30 min pulses, the radioactivity distributes on a progressively wider area, which extends beyond the nuclear matrix (Fig. 2*b*, *c*). The radioactive area expands at a rate of ~0.47 μm min^{-1} (see Fig. 2 legend), in agreement with estimates of fork movement rate from DNA fibre autoradiography[29]. Almost identical results were obtained in pulse-chase experiments (data not shown) in which the expansion rate of the radioactive area was ~0.43 μm min^{-1}. Taking account of the bidirectionality of DNA replication and the average loop size in *X. laevis*, one loop would be predicted to be duplicated in ~30 min; hence pulses longer than 30 min should not result in a further increase of the labelled area. This was confirmed after 60 min labelling, since there was no substantial difference in the size of the labelled area compared with after 30 min.

The expansion of radioactivity on the halo with increasing pulse length suggests that replicating DNA loops are reeled through matrix-bound replication complexes, as proposed by Pardoll *et al.*[15,30]. On this interpretation, a relationship between the average loop size and the average replicon length would be predicted. We have chosen several animal and plant species

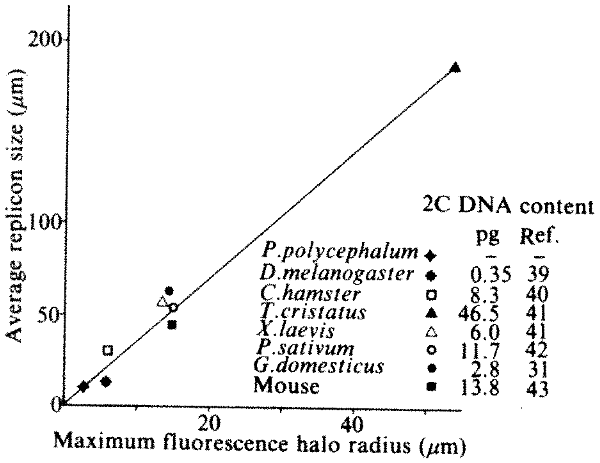

Fig. 3 Relationship between maximum fluorescence halo radius (MFHR) and average replicon size (av. RS). MFHR was determined by treating blood smears, cultured cells grown on microscope slides or isolated nuclei with ice-cold NP40 buffer and staining with 100 μg ml^{-1} ethidium bromide in high-salt buffer (see Fig. 1 legend). Maximal fluorescence halo expansion was induced by prolonged (⩾2 min) UV irradiation under the fluorescence microscope and measured using a micrometer eyepiece. Mean MFRH values (in μm) ± s.d. (number of measurements) are given below. MFHR data for *P. polycephalum* and mouse and all av. RS values (in μm determined by DNA fibre autoradiography) are taken from the literature. *P. polycephalum*: av. RS, 9[38]; MFHR 2.5–3[23]. *Drosophila melanogaster*: av. RS, on Schneider 2 cultured cells, 13.6[32]; MFHR, on GM 2 cultured cells (gift of Dr R. Caneva, Centro Acidi Nucleici, Rome) 6.0 ± 0.8 (25). Chinese hamster: av. RS, on B14FAF28 cultured cells, 30[33]; MFHR, on CHEF 125 cultured cells (grown in Eagle's minimal essential medium at 37 °C under 5% CO_2), 6.1 ± 0.7 (31). *X. laevis*: av. RS, on A6 cultured cells, 57.5[31]; MFHR, on kidney cultured cells (see Fig. 2 legend), 14.0 ± 3.2 (19). *Pisum sativum*: av. RS, on cells from root tip meristems, 54.7[34]; MFHR, on nuclei from root tips (isolation procedure as described in Fig. 4 legend) 14.8 ± 1.5 (25). *Gallus domesticus*: av. RS, on embryonic primary cell culture, 63[35]; MFHR, on freshly prepared blood smear, 14.1 ± 1.7 (15). Mouse: av. RS, on L929 cultured cells, 45.4[36]; MFHR, on 3T3 cultured cells, 15[11]. *Triturus cristatus*: av. RS, on liver primary cell culture, 188[31]; MFHR, on freshly prepared blood smear, 53.7 ± 4.2 (24). The 2C DNA contents in pg (ref. from which value is taken) for the various species examined are the following. *P. polycephalum* (◆), (—); *D. melanogaster* (★), 0.35[39]; Chinese hamster (□), 8.3[40]; *T. cristatus* (▲), 46.5[41]; *X. laevis* (△), 6.0[41]; *P. sativum* (○), 11.7[42]; *G. domesticus* (●) 2.8[31]; mouse (■) 13.8[43].

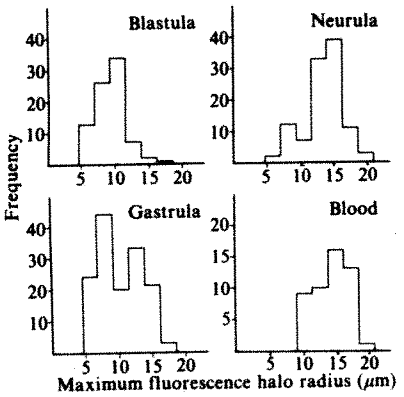

Fig. 4 Maximum fluorescence halo radius in different developmental stages of *X. laevis*. Ovulation and mating were stimulated by injection of gonadotropic hormone into the dorsal lymph sac a few hours before mating: females received 1,200 U of Pregnyl (Organon) and males 300 U. Mating and egg laying were allowed to occur overnight. The embryos were then collected, dejelled with 2.4% cysteine *p*H 7.5 and staged according to Nieuwkoop and Faber[37]. Nuclei were isolated by gently homogenizing the embryos in buffer A (60 mM KCl, 15 mM NaCl, 0.15 mM spermine, 0.5 mM spermidine, 15 mM 2-mercaptoethanol, 15 mM Tris-HCl *p*H 7.5) containing 0.34 M sucrose. One volume of ice-cold NP40 buffer (see Fig. 1 legend) was then added and the homogenate was centrifuged (~1,000*g* at 4 °C for 10 min) on a 1.37 M sucrose cushion in buffer A. the pellet was resuspended in a small volume of 20 mM EDTA, 10 mM Tris-HCl *p*H 7.5. A droplet of this suspension was diluted, directly on microscope slides, in an excess volume of 100 μg ml^{-1} ethidium bromide in high-salt buffer (see Fig. 1 legend) and covered with a coverslip. Maximum fluorescence halo radii were measured under the fluorescence microscope, using a micrometer eyepiece, after prolonged (≥2 min) UV illumination. Blood smears were treated for maximal fluorescence halo expansion as described in Fig. 3 legend. Mean values (in μm) ±s.d. (number of measurements): blastula (stage 8–9), 9.4 ± 2.4 (83); gastrula (stage 10–11), 10.3 ± 3.3 (145); neurula (stage 13–14) 13,5 ± 3.0 (107); (adult blood) 14.5 + 2.6 (49). The observation of fluorescent haloes on embryonic nuclei in suspension is quite difficult, as the DNA haloes, compared with those from blood smears or cells growing attached to glass surfaces (Fig. 3), can be easily distorted or destroyed by sudden currents or air bubbles in the liquid sheet between the microscope slide and the coverslip.

(Fig. 3) whose replicon sizes are known from DNA fibre autoradiography. The maximum halo radius seems to be species specific, varying from 2.5 μm (*Physarum polycephalum*) to 53.7 μm (*Triturus cristatus*), and is only roughly proportional to 2C DNA content (DNA content/diploid nucleus). On the other hand the halo radius (loop size) is directly proportional to the average replicon length, which strongly supports a general relationship between supercoiled loop structure and DNA replication.

It is of interest to speculate how DNA loops might be related to replication. A preliminary condition must be the existence of two adjacent matrix-bound replication complexes per replicon, in order to reconcile fixed replication sites with the bidirectionality of synthesis. As a further development of previous models[2,15,19,20,22,30] we propose that each replicon might actually correspond to two adjacent loops and be duplicated by the reeling of the DNA through a couple of matrix-bound replication complexes, alternate anchorage sites of the DNA to the nuclear matrix behaving as origins and termini of replication. Once a new nuclear matrix is assembled—whenever this happens with respect to the S phase—one of the two newly replicated origins, and one of the two termini, would remain bound to the old matrix while the other would bind to the newly assembled one. This, admittedly speculative, view was drawn from the data in Fig. 3. The average replicon length in all the species explored is roughly four times the maximum fluorescence halo radius, that is, twice the size of a DNA loop. Although the replicon lengths and halo radii are only approximations, our interpretation is appealing because it suggests how the whole chromosome structure can be faithfully reproduced at each cell cycle and how daughter DNA strands orderly segregate at mitosis.

An intriguing facet of DNA replication in multicellular organisms is the brevity of the S phase in early, compared with later, development. As the rate of fork movement is constant, the variation has been explained on the basis that during pregastrular stages, compared with later ones, the origins of replication are synchronously activated and the replicon size is smaller[31,32].

To check further the proposed correspondence between replicons and supercoiled loops we have determined the maximum halo radius in embryonic cells from *X. laevis* at pre- and post-gastrular stages. The maximum halo size in blastulae averages 9 μm (Fig. 4). A significant proportion of gastrula-stage nuclei are able to develop haloes of 10–15 μm, and at the tail bud stage, most of the dehistonized nuclei have 10–15 μm haloes. These results are consistent with the reduced replicon size in pregastrular stages[31,32] and further support a relationship between supercoiled loops and replication units[11]. They suggest that structural rearrangement of the chromosome occurs during gastrulation, when the embryonic genome enters a phase of active gene expression. However, the intrinsic limitations of the technique used here (see Fig. 4 legend) require that this structural transition be confirmed by different experimental approaches. It is nonetheless tempting to envisage such a transition in gastrula as of crucial importance in establishing novel patterns of supercoiled loop domains representing both replication and transcription units.

We thank Mrs M. T. Curtale and Miss T. Forte for carrying out some of the experiments on *X. laevis* fluorescence haloes, and Mr L. Lascari for technical assistance. This work was supported by grants CNR 78.01345.04 and 79.03191.04 to M.B.-N. M.M. was recipient of a NATO fellowship.

BOOK REVIEWS

Confronting the unanswerable

Marie Jahoda

The Mind's I: Fantasies and Reflections on Self and Soul. Composed and arranged by Douglas R. Hofstadter and Daniel C. Dennett. Pp.450. UK ISBN 0-7108-0352-4; US ISBN 0-465-04624-X. (Harvester/Basic Books: 1981.) £9.95, $16.95.

WHEN two nimble minds combine in the effort to produce a book designed, according to the preface, "to provoke, disturb and befuddle its readers" the chances of succeeding in this not obviously laudable enterprise must be high. Had Hofstadter and Dennett added to their aims amuse, disappoint and frustrate they would have encompassed the whole universe of possible readers' reactions to this particular book and their success, measured by their own standards, would have been total.

The themes addressed in the book concern eternal questions that have preoccupied great and not so great minds since the dawn of history: the nature of self, of consciousness, of reality, the body–mind problem, free will, the relation of mechanism to meaning. Every conceivable approach to these issues has in the past been adopted with conviction by some; none has withstood critical examination by others. All of them, however, whether based on religion, philosophy or science fulfil a major function: they enable their adherents to engage in a bootstrap operation, pulling themselves out of the inevitable ignorance about the ultimate why and wherefore. Once this operation is performed they can proceed to tackle answerable questions or develop consistent world views.

The debate about fundamental assumptions has in recent years gained new impetus through the development of computers and of artificial intelligence (AI); both play a dominant part in the book under review. The issues raised are, however, also tackled by other means without recourse to modern technology or to the spreading enthusiasm for AI. This variety of approaches is the result of the peculiar conception of this book. Hofstadter and Dennett have here reprinted pieces by 20 different authors, each of whom is known as a science fiction writer or a philosopher or a scientist or a literary figure. If one did not know their names it would be hard to classify them, for many write with remarkable ease in several of these idioms. Every contribution is followed by some reflections on it by one or both of the "composers" of this volume. These original contributions form less than a quarter of the text.

Many, though not all of the reprinted pieces are amusing and relevant to the major issues. My favourite science fiction writer, philosopher and scientist, Stanislav Lem, is represented by several pieces, outstanding among them *Non Serviam*, where his man-made creatures agonize about their origin and the qualities of their creator; agonize because the very essence of their being precludes the possibility of discovering answers.

The philosopher Dennett in his excursion into science fiction raises the fantasy of a disembodied brain kept functioning while connected to an empty cranium by radio links, thus directing a human body hundreds of miles away. In his reflections on his own story Dennett rightly says that the story "not only isn't true . . . but couldn't be true" (p.230) and is truly "outrageous" (p.231). On p.5, however, he commits himself differently by insisting that everything that is imaginable is hence possible in principle; befuddling with a vengeance and disturbing in raising the possibility of brain transplants.

Richard Dawkins in an excerpt from *The Selfish Gene* is at his well-known reductionist best, but he admits that the evolution of subjective consciousness is "the most profound mystery facing modern biology" (p.141). Thomas Nagel's question, "What is it like to be a Bat?", prompts an interesting discussion of the gap between subjective experience and objective fact and the not-unexpected answer that it is hard to know.

In his reflection on this contribution Hofstadter, who has so brilliantly demonstrated his ability to discuss profound problems playfully and with wit in his *Prelude . . . Ant Fugue* (reprinted in this volume), here lets himself down by raising some 50 rather silly questions, of which "What is is like to be Chopin's brother [he had none]?" is a typical example. Nagel's question posed the problem; 50 variations do not make it clearer. To be sure, he follows this with other reflections, some of them interesting, but less coherent than Nagel's argument.

Computer simulation and AI appear in many original and reprinted contributions; they are confronted head-on in John Searle's "Minds, Brains and Programs" and in the following reflections. This sharp and prolonged controversy forms the frustrating highlight of the book. Searle distinguishes the cautious claim of AI — that it is a powerful tool for the study of the mind — from the strong claim that computers given the right programs can be literally said to *understand* . . . the programs are not mere tools . . . to test psychological explanations; rather . . . themselves the explanations [p.353].

This claim provokes him to a sustained counter-argument, the gist of which is to insist on the difference between simulation and identity, based on the impossibility of separating mind from brain. Intentionality is a biological phenomenon . . . No one would suppose that we could produce milk and sugar by running a computer simulation of the formal sequences in lactation and photosynthesis, but where the mind is concerned many people are willing to believe in such a miracle . . . [p.372].

In their reflections on Searle, Hofstadter and Dennett say unequivocally "our position is quite opposed to Searle's" (p.373) but they do not proceed to face the issues straight on. By implication rather than direct statement they seem to support the strong claims of AI, though they admit that present technology has not yet established the identity of programmed intelligence and human intelligence. "Minds . . . may come to exist in programmed machines. . ." (p.382).

We shall all have to wait and see. Anybody who wishes to confront the unanswerable will enjoy this book; those who struggle with answerable questions will brush it aside.

Marie Jahoda is Professor Emeritus of Social Psychology and Consultant to the Science Policy Research Unit, University of Sussex.

Gentle violence

William H. Press

Violent Phenomena in the Universe. By Jayant V. Narlikar. Pp.218. ISBN 0-19-219160-8. (Oxford University Press: 1982.) £9.95, $19.95.

THE title of this book makes it seem like some tawdry imitation of Nigel Calder's *Violent Universe.* Perhaps some editor with an eye on sales can be blamed for such a blatancy, which does disservice to a excellent and uncompromising book on modern astrophysical theory and discovery. Not just inapt, the title seems quaintly *passé*: "violence" as a cosmic metaphor seems to have faded with the early 1970s. And who now remembers the "majestic" universe, before it became violent?

The universe through which Narlikar ads us is more rational than violent. Its phenomena can be discovered, explored and understood by careful analysis. Moreover, the facts and their analysis can be laid open to the scrutiny of the non-specialist reader.

Precision and economy of expression characterize the narrative as it takes the reader through prerequisite discussions of Newtonian gravitation (and its successful celestial mechanics) to Einstein's theory of gravitation, and then to quite a sophisticated discussion of the formation of black holes and the laws of black-hole physics. The emphasis then waxes astrophysical for a few chapters: stellar evolution, supernovae, neutron stars. By now the reader is ready for pulsars, binary X-ray sources, accretion disks, X-ray bursters, and then a chapter on active galaxies and quasars. The material is extremely up-to-date.

Finally, there are two chapters on cosmology. The first is a clear (if conventional) summary of the big bang, synthesis of the chemical elements, its observed echo in the cosmic microwave background. The second, unfortunately, is on the author's own alternative theory, one favoured by virtually no other practising cosmologist. The author is absolutely fair in introducing this chapter as a "non-standard" and "minority" view; but one is left wondering why he did not apply the same rigorous standard to this chapter as to the previous ones, and delete it *in toto* (an action which the reader should take on his own).

Several stylistic features set this book apart from the myriad other popular and semi-popular books on "black holes and all that stuff": its richness of factual detail; the implicit sophistication in its presentation of the scientific process, the interplay of observation with theoretical hypothesis; its uncompromisingly literate *and numerate* prose. Algebraic formulae are used freely; the reader is assumed to be comfortable with the use of symbols and numbers to represent physical quantities. Further, a sane, methodical organization pervades the whole book. A typical subchapter begins with a question, such as "Does the X-ray source Cygnus X-1 contain a black hole?". Observational facts are then concisely presented, before the author proceeds to discuss the bearing of each of the facts in turn on the question posed.

Probably too sophisticated for a lowest-common-denominator "popular" audience, this book can be recommended strongly to anyone with at least an undergraduate degree in any scientific subject who wants a precise narrative presentation of the excitement of modern astrophysical discovery — and no danger of being talked-down to! □

Self-instruction in high energy physics

Maurice Jacob

Basics of Electron–Positron Collisons. By Fernand M. Renard. Pp.238. ISBN 2-86332-010-6. (Editions Frontières: 1981.) FF150, $30.

WITH the decision to build a Large Electron–Positron storage ring at CERN, the LEP project, a large part of future European activity in high energy physics became invested in the study of electron–positron interactions. Already, a tremendous wealth of results has been collected from the e^+e^- colliding ring machines at Stanford (SLAC) and Hamburg (DESY); the LEP project will further extend our ability to investigate the intriguing phenomena thus revealed.

Professor Renard's book on the basics of electron–positron collisions therefore comes at a particularly appropriate time. Many students and experimentalists wish to familiarize themselves with calculations which, over and over again, crop up in the analysis of such collisions. The book should be a good self-teaching guide for that purpose. The author surveys all the standard cases in great detail, giving both explicit formulae and enough of the intermediate steps for their derivation *ab initio*, while always being meticulous with notation. However, in his gallic approach he has a tendency to start with the most general case, discussing only later simpler particular cases, when the beginner might have found the reverse more helpful. The presentation is nevertheless clear enough to enable the reader to skip the general sections easily and go directly to the specific examples.

Reading this book, and making the effort to derive the many formulae given, should prove a very worthwhile investment of time for the dedicated student with some background in relativistic quantum mechanics. The numerous formulae which it contains will also make it useful to the experimentalist writing a Monte Carlo program to assess the response of a detector to expected reactions. To that extent, the book certainly meets a need.

This said, I should add that the newcomer to the field might feel frustrated at the paucity of figures, when the wealth of experimental results is such that calculated distributions and concepts such as jet structure could have been beautifully illustrated. The surprising absence of graphs or tables is also a serious drawback for the reader wishing to assess which kinematical configurations are the most appropriate for the observation of any particular process. For that reason it is difficult to recommend the book as a reference text; it is pitched, perhaps, too much at the computational level when one could have wished for a more global phenomenological approach. Also, while the scope is quite exhaustive, some sections should be considered merely as brief introductions to particular areas which have come into bloom only recently; this applies especially to the account of quarkonia and jets.

The book thus falls short of providing a balanced, critical survey of research on electron–positron collisions. It should, however, definitely be considered as a useful tool for the dedicated physicist entering this active and exciting field. □

Yale University Press have recently re-issued Richard Goldschmidt's *The Material Basis of Evolution*, first published in 1940. The reprint incorporates an introduction by Stephen Jay Gould and, in his words, "commemorates a strong reawakening of interest in Goldschmidt's views among evolutionary biologists". Prices are hbk $35, £25; pbk $12.95, £9.

Dark reactions

M.C.W. Evans

Photosynthesis. Proceedings of the Fifth International Photosynthesis Congress. Edited by G. Akoyunoglou. Six volumes, pp.5,322 excluding indexes. ISBN 0-86689-012-2. (Balaban International Science Services: 1982.) $499. Single volumes also available. Distributors ISS, S. Pomerantz, 2242 Mt Carmel Ave., Glenside, PA 19038; ISS, Couwenhoven 62-49, 3703 HN Zeist, The Netherlands.

I MUST start this review with two admissions: first I am an author of a very small part of the books under consideration, and secondly I have not read very much of them. However, probably neither is a serious disability. Almost anyone who might review them is an author, and it is highly unlikely that anyone will ever read the entire work. It has 5,322 pages, plus 69 pages of index repeated in each volume, at least 10 million words, and weighs nearly 9 kg. It contains 650 papers written by 850 authors ranging from Abdourakhmanov, I.A., to Zurrer, H., who achieve authorship of between 1 and 13 papers each.

Enough statistics. The books contain the proceedings of a very successful conference held in Halkidiki, in Greece, late in 1980 (see *Nature* **289**, 122; 1981). They appear 18 months after the meeting and the question must be, was their publication necessary or worthwhile? The papers are unreviewed and cover a very wide range of subjects from the biophysical studies of light absorption in the picosecond time range, through biochemical work on CO_2 fixation, genetic analysis of chloroplast DNA, to physiological ecology. The wide range of subjects is of course a problem for the organizers of the triennial photosynthesis conference, but on balance it is probably a good thing for researchers at the extremes of photosynthesis research to have the chance to hear each other every so often. However they are unlikely, having listened to the talks, to read them again two years later. This is admitted by the editor, who has packaged the volumes into specialist areas for separate sale: the intention does not, then, seem to be to spread a wider view of the world.

Do the books contain much important information which is not available elsewhere? They certainly provide a total view of photosynthesis since so many people attended and dutifully handed in their manuscripts. Much of the work described is of course first class, but even for the best only an outline is provided in the space allocated. For major laboratories a few touches on the world randomizer overcame copyright problems, while for lesser mortals the opportunity to unload all that important work that the refereed journals didn't understand was not to be missed. It is really very unlikely that these volumes contain anything of major scientific importance which has not been published previously: indeed, the smart conferee knows better than to mention anything not already in press with a "good" journal.

Why then did the organizing committee publish the books, and why did the authors bother to submit their papers? The latter question is perhaps easier to explain. Invited speakers no doubt feel some duty to meet the organizers' requirements, while few of us can resist a "free" publication, although surely everyone who is supposed to be impressed by publication lists automatically discounts proceedings of this type. Why the organizers should want to record the proceedings in full is rather harder to understand. There is surely little money to be had from them and an enormous amount of work must have gone into their production. At the Fourth Congress in this series, held in England, no such book was produced, and I do not believe it was seriously missed. It is to be hoped that the organizers of the Sixth Conference next year will show similar restraint.

Who might buy one or all of these books? Libraries, for student use? — review volumes and textbooks are a far better buy. Research laboratories? — refereed journals offer virtually all the useful information. A souvenir of an excellent conference? — a case of ouzo and a set of pornographic coasters would be more fun. No! These volumes are really only for the man who has everything. □

Philosopher at the bedside

W.F. Bynum

Medical Thinking: A Historical Preface. By Lester S. King. Pp.336. ISBN 0-691-08297-9. (Princeton University Press: 1982.) $19.50, £14.50.

BRILLAT-Savarin's *Philosopher in the Kitchen* showed long ago that every human activity — even cooking and eating — is enhanced by due philosophical reflection. Lester King's philosopher has moved to the bedside where, *malgré lui,* he juggles philosophical concepts when examining his patient, making a diagnosis or prescribing a course of therapy. In using words such as *sign, symptom, syndrome, health, disease, normal, pathological, cause,* and *effect,* any doctor engages in language possessing a philosophical dimension. The quality of his medical thinking will be reflected in the precision and consistency with which he employs these and similar words. The purpose of King's book is to sharpen that thinking by the historical and philosophical glosses he provides on this central core of medical concepts. It is, King asserts, the kind of book he wishes he had had when he began medical school more than half a century ago.

King's credentials are impressive. After spending 30 years as a pathologist he became a senior editor of the *Journal of the American Medical Association,* a position which permitted him to devote a good deal of time to medical history. His historical researches have ranged widely, but he is a particular student of seventeenth- and eighteenth-century medicine. Those who have followed his earlier work will have noted its increasing philosophical preoccupation; they will also be familiar with many of the doctors — Daniel Sennert (1572-1637), Thomas Sydenham (1624-1689), Hermann Boerhaave (1668-1738), William Cullen (1710-1790) — who people the present volume. Throughout, there is a mixture of historical and contemporary material, as King seeks to identify certain constant features in the interactions between doctors and their suffering patients.

King's central theme may be baldly stated: there has always been good medical thinking, as well as bad, even though medicine's conceptual framework and the amount and quality of medical information available to a doctor have changed dramatically over time (and particularly in the past century or so). In one of the best chapters of the book, King illustrates this constancy in the midst of change by showing how the diagnosis of pulmonary phthisis evolved from the seventeenth to the late nineteenth century with the gradual abandonment of Greek humoralism, development of the tissue concept, invention of the stethoscope, increased use of microscopes and cell theory, and the emergence of bacteriology. The change in name from phthisis to tuberculosis was part of this process, but pulmonary phthisis was not simply the old name for tuberculosis. Rather, it was a separate disease, often of course including patients suffering from what we would call tuberculosis, but a disease which must be understood historically, within the intellectual frameworks of earlier times. Thus, Richard Morton (1635-1698) cannot be blamed for describing a different disease from the one which intrigued Robert Koch (1843-1910), nor does the fact that Koch worked with 'our' tuberculosis mean *a priori* that he was a better thinker than Morton. Good medical thinking is reflective, critical, and consistent, but is also historically contingent.

The other chapters of King's book are arranged primarily around those concepts intrinsic to medical diagnosis. He examines the historical relationships between signs and symptoms, between concepts of health and of disease, between the 'clinical entity' and the 'disease entity', between disease classification (nosology) and medical knowledge. He has useful things to say on all these and other topics, but some readers may find that three characteristics limit the book's scope. First, it is an extremely personal statement. Many of his references to the secondary literature are to his own earlier writings, and even when citing other work of direct relevance to his topic — for instance A.R. Feinstein's *Clinical Judgment* (Williams & Wilkins, 1967) or F. Kräupl Taylor's *The Concepts of Illness, Disease and Morbus* (Cambridge University Press, 1979) — he makes little attempt to place his own position within its contemporary context. While this gives King's book a greater internal coherence, it also unnecessarily isolates it.

More important, perhaps, is the relatively narrow perspective of disease which King espouses. He is aware of the cultural relativity of disease categories (Chinese women with bound feet are diseased by Western standards), and of the aesthetic judgements which enter definitions of health (straight teeth are 'healthier' than crooked ones). But King's own concept of disease is essentially lesion-orientated. Thus, there is nothing on the notion of mental disease, or of 'functional' illness, or psychosomatic medicine. These softer edges of contemporary medicine are important dimensions of current debate and deserve explicit treatment in a book which is designed to sharpen medical thinking.

Finally, King's philosophy of history has a surprisingly thin social base. Despite his wise injunctions to us to view historical characters historically, he fails to put Sydenham or Cullen in any concrete social milieu. Even epidemiology gets short shrift, an unfortunate omission in two otherwise perceptive chapters on historical contemporary concepts of disease usation. It would seem from King's nalysis that medicine has its own internal impetus for change, whereas most historians would place more emphasis on social and professional factors.

These lacunae in King's book by no means negate its value. It is a work which repays thoughtful reading, not least for the way it laments sloppy medical thinking in any age, our own included.

W.F. Bynum is at the Wellcome Institute for the History of Medicine, London, and a co-editor of the Dictionary of the History of Science *(Macmillan/Princeton University Press, 1981).*

Unity in diversity — or how to choose your animal

R.B. Moreton

Membrane Physiology of Invertebrates. Edited by Ronald B. Podesta. Pp.664. ISBN 0-8247-1503-9. (Dekker: 1982.) $87.50.

IN THE animal kingdom, invertebrates not only outnumber the vertebrates to an unimaginable extent, but also present a fascinating diversity of form and function, combined with a surprising unity of basic mechanisms. To those of us who study a specific tissue in depth this provides an opportunity to pick those animals where the particular tissue is especially large, simple or well-developed. Thus, as every physiologist knows, the squid has a giant axon, the sea-urchin lays eggs, the crayfish has a stretch-receptor, and so on. This theme is developed by the late P.C. Caldwell in the introduction to this book, and it runs through the entire volume despite efforts by some authors to collect more general information: invertebrate physiology is just like that.

Membrane Physiology of Invertebrates is a collection of essays by specialist authors, arranged roughly in order of complexity of the organisms covered. It begins with an outline of our disappointingly sketchy understanding of how *Amoeba* feeds, and a detailed analysis of the electrophysiology of the "slipper microbe" *Paramecium*, whose genetic variations have been exploited to study particular membrane functions in isolation.

A chapter on coelenterates (jellyfish and hydroids) provides interesting examples of specialized intercellular junctions, and of the way in which development, for example the growth of new "heads", is controlled by cellular secretions. Intercellular junctions are still more important in the helminths, dealt with in the next contribution, where whole sheets of cells can be fused to form the body-wall. Annelids are covered in chapters on epithelial transport (osmoregulation, digestion and excretion) and excitble cells. The former presents a mainly qualitative study of "what happens where"; the latter begins with a rather confusing attempt to compare the properties of nerve cells in leech and earthworm with those of other groups, but gets into its stride with quantitative modelling of the giant axon of *Myxicola.* Crustacea are treated similarly, with a detailed and well-illustrated chapter on the gastrointestinal tract, and a good summary of the diverse types of nerve cells and sensory organs that have been studied, including a brief section on barnacle photoreceptors. A chapter by G.A. Gerencser on molluscan digestion presents mainly the author's own work, but refers to other reviews on osmoregulation and transport across the body-wall. The much larger pool of knowledge on molluscan nerve cells is covered, inevitably rather selectively, by F.E. Dudek, who concentrates on gastropods — perhaps enough has been written about the squid axon for the time being! Dudek does include neuromodulators and neuropeptides, however, usefully integrating this relatively new topic with more conventional ideas on synaptic transmission.

Insects are represented by a contribution on gut physiology by W.R. Harvey, which includes an exposition of the thermodynamics of active transport systems, and by a neat summary of the properties of insect muscle, written by F.M. Ashcroft. There is no chapter on insect nerve cells, perhaps due to lack of space to treat this large subject properly. The book ends, unexpectedly, with a short chapter on the echinoderms, dealing mainly with the interesting electrical and chemical events accompanying fertilization of the egg.

This is not a book for the novice: most of the material is detailed and technical, with a fair amount of theory. Rather, it gives a comprehensive view "over the fence" for the specialist in transport or excitable tissue physiology, or for the researcher seeking to enter a new field. The title is misleading, in that much of the material relates to whole epithelia rather than membranes as such. But as a summary of our current knowledge of epithelial transport and excitable tissue physiology, right accross the invertebrate kingdom, the book is about as up-to-date as can be expected given the inevitable publication delays. Certainly, it should be in every library. ☐

R.B. Moreton is a Principal Scientific Officer with the ARC Unit of Invertebrate Chemistry and Physiology, Department of Zoology, University of Cambridge.

Molecular shapes

M.G.B. Drew

Inorganic Stereochemistry. By David L. Kepert. Pp.227. ISBN 3-540-10716-9; 0-387-10716-9. (Springer-Verlag: 1982.) DM154, $71.70.

CHEMISTS have always had a fundamental interest in the shapes of molecules and in evaluating the reasons for the adoption of a particular geometry. There are two theoretical approaches to such problems: the minimization of non-bonded repulsions and molecular orbital calculations. In this book, Professor Kepert uses simple repulsion theory to evaluate the various geometries of the metal coordination spheres of inorganic complexes in which one central metal atom is surrounded by 4–12 donor atoms.

The author takes each coordination number in turn and calculates the potential energy surface, allowing for possible combinations of unidentate and multidentate ligands. The theoretical results are then compared to the observed structural data provided by X-ray analysis. The enormous amount of structural information is thoroughly assimilated and well organized. There is excellent agreement between theory and experimental data, and in all the book amply demonstrates the validity of the repulsion approach to stereochemistry.

Kepert's work has undoubtedly been a major contribution to our understanding of molecular geometry. However it does not seem to have had much impact on the way in which chemists look at molecular geometry. There are probably two main reasons for this. First, the parameters used for the potential energy curves are often not simple to calculate; structural chemists prefer to analyse geometry on the basis of bond lengths, bond angles and δ angles and find Kepert's parameters unnecessarily complicated. Secondly, he does not compare his results with those obtained by other methods. To take just one example, many people find that δ angles are useful structural parameters but they are not mentioned here. Nor indeed are the results of molecular orbital calculations.

It is this single-mindedness that is both the strength and weakness of the Kepert approach: whilst the book is self-contained, it is not intended to provide a balanced view of current ideas on stereochemistry.

It is certainly useful to have Kepert's work brought together in one volume. However the book follows closely a series of reviews written for *Progress in Inorganic Chemistry* over the past few years, and those who have the previous articles may well find this present volume of limited additional value.

M.G.B. Drew is a Lecturer in Chemistry at the University of Reading.

Who sells to the Soviet Union?

The Reagan Administration will probably decide to extend the grain agreement with the Soviet Union for a year. Can it then insist that West European governments should not buy gas from the East.

With the best will in the world, it will be hard for Europeans to be charitable about last week's special cabinet meeting called by President Reagan to help him decide whether United States farmers should continue to sell bulk cereals to the Soviet Union when present arrangements run out in September. Naturally, there will be much sympathy for Mr Reagan's dilemma. By denying it access to the Middle West, he could cause the Soviet Union a great deal of inconvenience (the need to shop around for other grain), physical discomfort (hunger) and even occasional starvation while establishing the powerful political point that United States farmers are more efficient than their Soviet counterparts. He would also provide the Soviet Union with a reminder that the *de facto* occupation of Afghanistan still rankles. These are great prizes, not lightly to be dismissed. But unfortunately for Mr Reagan, there is another millstone pressing on him — the unwillingness of farmers in the Middle West to sacrifice their occupations and their holdings by becoming bankrupt (more common already in the past twelve months than for several decades) in the cause of talking toughly to the Soviet Union. Politicians in most places will be full of fellow-feeling for the president. Especially because this is a mid-term election year (and because a decision must be made before polling day) they will weep with him as he sacrifices principles on the altar of prudence and renews the Soviet grain agreement for just one more year. But European politicians, no less given to calculations of how to square beliefs with the ballot box, will be asking why their acknowledgement of President Reagan's difficulty is not reciprocated in the matter of the natural gas pipeline between the Soviet Union and Western Europe.

That issue is more important than anybody in Washington seems to understand. (Mr George Shultz has made tactful noises, but is too new in his job as Secretary of State to be persuasive.) So far, three countries in Western Europe (France, Switzerland and West Germany) have committed themselves as customers for Soviet gas, and have agreed to make credits available for the construction cost of this gigantic project. (This in itself is not unusual; when did it most recently occur that Westinghouse, General Electric or Babcock-Wilcox built a nuclear power station n the hope of being able to sell the electricity production to some utility?) Sensibly enough, the countries concerned have done their best to ensure that they will not have to pay out too much (in the orm of convertible currency) in advance by securing Soviet agreement to buy in much of the advanced equipment that will be needed. Washington has for the past six months been doing verything it can to ensure that such agreements will not be ulfilled — and that the Soviet Union will have to look to other uppliers or even make the equipment for itself. Since the summit meeting a few weeks ago at the palace of Versailles, the governments of Western Europe have been bubbling with esentment at President Reagan's Administration's ruling on this question. How can one government tell commercial corporations egally registered under another's laws that they should renege on what is otherwise a binding contract?

Western Europe's sin, on President Reagan's view, goes even eeper — its willingness to pay out convertible currency year after ear in return for natural gas that may serve to keep its people warm and its industries in business but which will have the side-ffect of helping the Soviet Union to pay its bills and will make Western Europe strategically dependent on the East for a substantial part of its energy consumption. When Washington first woke up to the problems of the pipeline project eighteen months ago, it was principally alarmed at the prospect of strategic dependence, now mercifully seen in a less clear light. The present concern seems principally to deplore any arrangement that will make it less likely that the Soviet Union will cease to function overnight, and which may even offer it some assurance of an income-stream for thirty years or so. The long-term nature of the pipeline agreement is admittedly a more solemn undertaking than the one-year extension of the grain agreement that Washington now contemplates, but Western Europe could presumably repudiate its inital investment in the pipeline if the going became rough (or the price of gas too high). President Reagan is probably under-estimating the friendliness of his friends in Western Europe (one disservice) and is certainly bullying them too much by his complaints about the pipeline (another).

All this is especially disconcerting at a time when the Reagan Administration is in the box of having to talk to the Soviet Union, most days at Geneva, about the future of strategic arms. That contradiction is awkward and not easily avoided. Washington needs a Moscow willing to talk about strategic arms, but properly insists on its right to be huffy about Afghanistan and other transgressions. It wishes that it could also afford the luxury — all those farming votes — of standing firm on principle. Detente, the saying seems to be, is from time to time an expedient necessity. Western Europe, on the other hand, with no choice but that of being within a few minutes (by Intermediate Range Ballistic Missile) from the border, believes and behaves differently. Interdependence is a fact of life, but does not preclude the sudden breakdown of coexistence. The wisdom of the pipeline deal, in other words, is judged by relatively short-term criteria; for a half-continent whose separate existence could be quickly ended, long-term economic deals (lasting, say, thirty years) count for less than longer-term cultural connections — the sense of deprivation springing from people's inability to visit European cities such as Prague, Warsaw or even Leningrad when they choose.

Muddle about universities

The British government only seems to threaten university autonomy, but the precedent is bad.

Is the independence of the British university system, traditionally assured by the existence of the University Grants Committee as an intermediary between the government and the universities, now threatened? This is the obvious question provoked by last week's open letter to the committee from Sir Keith Joseph, the Secretary of State for Education and Science in the British government. For the letter, described as the first exchange in a "dialogue" between the government and the universities, finishes with the declaration that, in the development of British higher education and of the universities in particular, "there will be some strategic decisions for which it would be appropriate for ministers to take explicit responsibility and to answer in Parliament". After more than two years of abysmal relations between the government and the universities that it supports, beginning with the decision in the summer of 1979 that

028-0836/82/29031302$01.00

nceforth overseas students should pay arbitrarily defined economic fees", and with the later and equally arbitrary decision that direct support for the universities must be reduced by 8.5 per cent, it is natural that the universities should assume that the minister's intentions towards the University Grants Committee are malevolent.

Some consideration should therefore be given to the more or less moderate tone of the bulk of the Joseph letter, which among other things repeats the promise that direct support for the universities will level out when the academic year 1983–84 is over (at least if inflation does not run away again), pats the grants committee on the back for its selective distribution of reduced funds among British universities, applauds the more recent decision to allocate extra funds to biotechnology (see *Nature* 20 May, p.173) and sympathizes with the general concern that, as things are, the recruitment of "young able people" into the university system is virtually impossible. The letter even acknowledges that the grants committee has acted sensibly in revising some of the targets for student numbers at particular universities in the light of some special pleading, even though these decisions will marginally shade the government's insistence that student numbers should be fixed from on high. How, it may be asked, can such a reasonable minister have malign intentions towards the independence of the system?

On the evidence of the minister's letter, part of the trouble is simply that the British government remains in a muddle about higher education. Student numbers are a good illustration. The most illiberal feature of the present university contraction is that each British university has been given a ceiling for the number of students from the United Kingdom and European Community countries it can have on its books in 1983–84. The result, since most numbers are reductions, is that much educational plant will be less than fully used and that universities will not be able to work their way out of financial trouble by doing their jobs more efficiently. (The threat that if they take in more than their allotted quota of students they will be penalized financially has not been withdrawn even though the grants committee did not repeat it in the letters sent to individual universities in May.) Yet this offensive system, and the uncertainties that go with it, arises simply from the government's fear that if the universities exceed their quotas, the cost will be increased of maintenance awards to students, paid by local authorities but then laid off on the central government. Is it really beyond the wit of a government anxious to play a more active part in the planning of higher education to devise some different system of subsidizing students, one that would combine the legitimate objective of controlling the total cost with flexibility on numbers?

The Joseph letter is also muddled about the relationship between the universities and the higher education institutions formally supported (but with funds from the central government) by local authorities, chiefly the polytechnics. The coexistence of these two kinds of institutions in what is called the "binary system" is strictly a political matter, for the polytechnics were established (in the 1960s) because of the then government's conviction that there was a need for a more down to earth system of higher education than the universities chose to provide. The experiment has been only a patchy success but, to its credit, the present government has been trying since before Sir Keith Joseph's time at the Department of Education and Science to wrest full control of the polytechnics away from the local authorities. Indeed, there is now a National Advisory Body for the polytechnics in England, and there may soon be one for those in Wales. The Joseph letter now asks that the grants committee and its counterpart committee for the polytechnics should consult with each other and that, as well as working out schemes for collaboration between individual universities and polytechnics, they should also help to define the relationship between the two sectors of higher education. The objective is sensible and should have been sought a long time ago. But the issue, eminently political as it is, must in the long run be settled by the government.

What the Joseph letter says about the support of university research is more alarming. The letter applauds the grants committee's intention to play its part in the dual support system, welcomes the Merrison report on the subject and goes on to approve of the principle that there should be "selectivity of funding" not merely by the research councils that provide project grants for university research but also by the grants committee, which is responsible for supporting a "basic level of research activity". What, suspicious minds will ask, is the minister approving? A decision, not yet taken, that in future there will be two kinds of universities — those equipped for research and those which are not? The Merrison committee rightly argued that British universities are less deliberate than they should be in using the grants committee's general subvention for research, and acknowledged that even if the job were done intelligently, some university departments would be able to mount research programmes only in collaboration with others. But the Merrison committee also rejected the principle of a close correlation between research support provided by the grants committee and the research councils, for that would only undermine the dual support system as a whole.

The fear that the Department of Education and Science does not properly understand the system of higher education in whose management it now seeks a more decisive role is the worry underlying the declaration that in future ministers must take more responsibility for it. Higher education may be too important to be left to academics, but the British government hardly seems their natural successor. By all accounts, the present intention is merely that Sir Keith Joseph should from time to time give the grants committee general guidance about its sense of where priorities lie. The difficulty is that the government's sense of priorities is unlikely to make academic sense. The present concern is somehow to shape higher education so as to contribute to national prosperity, a question with which university systems elsewhere than in Britain have wrestled for decades, but without much success. The danger is that from frustration, ministers will slip into the habit of making their priorities particular, issuing edicts such as "Let there be more engineers!", "Let there be more computer engineers!" or even "Let there be more computer engineers training on British equipment!" Sir Keith Joseph himself may be aware of the dangers. But once the precedent of intervention has been established, his successors will be provided with countless opportunities for foolish interference.

Pity the luckless British

Great wars are said to bring out the best in people. Small wars appear to reveal the worst.

Who would have predicted that a mere month after a famous victory in the Falklands, the British government would be deeply embarrassed by a concatenation of domestic blunders — the false assumption that it would be able to comply with its bargain with its opponents when it won consent to send an amphibious force to the South Atlantic by mounting a Parliamentary enquiry on its own terms of reference? the discovery that an intruder could climb into Buckingham Palace and sit on the Queen's bed for ten minutes before being apprehended? and the growing likelihood that there has been another monumental breach of national security at one of the most technically advanced intelligence centres in the world? The British legend, especially common since the Second World War, is that the British are good at fighting (and even winning) wars but less endowed with flair in times of peace. The truth is different, as the events of the past few months have shown all too clearly. Most probably, the Parliamentary enquiry will show that the Falklands war was unnecessary, if not the consequence of a poor appraisal of intelligence then of indolence. Much the same is likely to be the case of the other conspicuous failures of public administration in the past few weeks. But who, or what, is to blame? The simple answer is the Civil Service, and its perennial pride in its technical innocence. The charge that this is so has been made repeatedly, and most governments have agreed that it is correct. When will one of them do something?

JPL takes on classified research

General to be appointed as new director

Washington

General Lew Allen Jr, who recently retired as chief of staff of the US Air Force, is reported to be the leading candidate for the directorship of the Jet Propulsion Laboratory (JPL), managed on behalf of the National Aeronautics and Space Administration (NASA) by the California Institute of Technology (Caltech). An announcement of the appointment is expected in the next few weeks.

The selection of General Allen would intensify the concern of some scientists at Caltech and JPL over the growing military role of the laboratory. Last year, the Caltech faculty and NASA agreed that up to 30 per cent of the laboratory's operating funds might come from Department of Defense (DoD) research contracts. Before that, the laboratory had refused to do classified research, under a policy laid down by Dr Bruce Murray (who ceased to be director of JPL on 1 July). The decline in NASA funding prompted Dr Murray to seek a change in that policy.

Dr Marvin Goldberger, president of Caltech, maintains that neither that change nor the appointment of General Allen — who he says is a "serious candidate" — will affect JPL's fundamental character. "We have every intention that JPL shall have its primary objectives in the civilian space programme. I can assure you that General Allen's view is coincident with this view."

A JPL scientist involved in the selection process pointed out that Allen has a strong technical and management background. He holds a PhD in physics from the University of Illinois, and worked at Los Alamos from 1954 to 1957. Allen directed the Air Force space programme from 1965 to 1972.

Allen declined to comment on the report that he is the principal candidate for the JPL position, and would say only that any announcement would come from JPL. But JPL officials are clearly worried about reaction to the appointment of General Allen, both within the Caltech-JPL community and outside it. Similar worries prompted the laboratory to adopt a tacit policy of not carrying out weapons research and development even with the lifting of the prohibition on classified work. The laboratory also made clear that it would not do "secret work secretly" — that is, it would only accept such classified projects as it could at least announce its participation in.

Dr Goldberger stresses, too, that work for DoD is subject to scrutiny by a faculty committee which reviews its "propriety" and its effect on the "overall mission of the laboratory". He also insists "classified work will not jeopardize access to the laboratory by Caltech faculty and students".

Dr Arden Albee, JPL's chief scientist, agrees that these precautions are enough to ensure that JPL remains fundamentally a NASA laboratory. "Certainly it's something we have to worry about, but my own feeling is it's not going to cause a significant change in the character of the place", he said.

"I KNOW THE PAY'S GOOD—
IT'S THE NEW LAB-COATS
I DON'T LIKE."

JPL's principal function within NASA is to provide the engineering and scientific support for unmanned planetary exploration missions. Some of this responsibility is shared with NASA's Ames and Langley laboratories, although JPL is the "lead centre".

At present, "about 8 or 9 per cent" of JPL's support comes from military contracts, according to Dr Albee. These are mostly "small technology projects" involving simulation, sensing and surveillance. The only large project is the autonomous spacecraft project which arose from the Voyager spacecraft work and is of some interest to the Air Force.

Nor does Dr Albee see any new threats to the scientific mission of JPL from its increased involvement in DoD projects: "NASA has always been a development agency; science got done on its periphery. That's as dangerous to science as DoD projects." He also points out that more research is supported by DoD on the Caltech campus than at JPL.

We have to put it in perspective," he said. "DoD is a major part of the budget. NASA is a small part."

JPL's current budget is $321 million; the laboratory employs a full-time staff of 4,620. The proposed budget for 1983 is $330 million, which represents a cut in real terms. According to Dr Arden Albee the most telling indicator of falling NASA support is that the laboratory has not started on a new planetary mission for almost 10 years.

Stephen Budiansky

France ponders biotechnology

France has done no microbiology for 20 years, has few people who understand fermentation or fungi and has never developed food processing technology. This wild exaggeration is the opinion of a francophile British biotechnologist sketching the problems facing France in his field. Now, however, a fairy godmother has waved her wand: the ministry of research and industry in Paris has published a vast programme for biotechnology, to stretch over three years and cost the government FF 600 million (about £50 million). Will she get Cinderella to the ball?

It depends in part on what the report says in a large section marked "Secret and Confidential", which has not been published but which describes the actions to be taken by the ministry in concert with industry. And it depends on whether France can create enough microbiologists, whose star fell faster and further in France than elsewhere when molecular biology turned to the eukaryotic genome. The University of Strasbourg, for example, was granted a new professorship in microbiology last year, with emphasis on biotechnology; it has been unable to fill it, said a spokesman, with anyone with even a smattering of French.

The ministry's three-year programme promises to tackle the problem in partnership with the universities and the *grandes écoles*. And the Centre National de la Recherche Scientifique (CNRS), which supports much of the most advanced biology in France, plans to help double the number of French microbiologists.

Meanwhile, several important centres of biotechnology will now enjoy increased support. At Toulouse, for example, there are three laboratories grouped to form a kind of "transfer centre" between research and industry, directed by Professor Jean-Pierre Zaltar (a specialist in gene expression). At Marseilles, there is a laboratory for bacterial microbiology, which will be expanded next year with the help of Orsay biochemist Jean-Claude Patte. At Cadarache, there is a new laboratory for biomass studies run by CNRS in conjuction with the oil company Elf Aquitaine and the Commissariat à l'Energie Atomique. At Compiègne there is the University of Technology with Dr Daniel Thomas specializing in enzyme technology; in Paris, the Institut Pasteur is

0028-0836/82/290315-02$01.00

working hard to make up for past years; and at the University of Strasbourg, there are well-advanced plans for a laboratory of plant genetics (which is, incidentally, strongly supported by the new report).

This week's report surprisingly emphasises the plant sciences, with no fewer than ten recommendations for INRA, the agricultural research body. Even Professor Roger Monnier, director of life sciences at CNRS, believes plant science must receive the most attention.

Over biotechnology as a whole, the report considers France to be weakest in bioengineering — in the kinetics of growth and production, in techniques of culture of microorganisms and cells, in enzymology, in reactor design, in extraction and purification and in the provision of analytical control equipment. France also suffers because of an "excessive compartmentalization and specialization of disciplines, research organizations and industries" says the report. But it ends on a strong note: now more than ever, France must support fundamental research, which is "the unique source of the unpredictable".

British Telecom

Roll up!

The British government is embarking on the most significant phase in its plans to liberalize the telecommunications industry. Mr Patrick Jenkin, Secretary of State for Industry, said this week that he will be introducing legislation in November to sell off British Telecom (BT), the state-owned telecommunications monopoly. The subsequent sale of shares will be the "largest single issue on the London market and maybe the world".

The sale of British Telecom has been widely forecast. Earlier in the year it was suggested that the government was considering privatization to avoid acting as guarantor for the company's borrowings. This week, Mr Jenkin confirmed this. But the government clearly hopes that British Telecom will be able to keep down its customer charges, which have recently risen above the cost of services, simply to finance 90 per cent of the annual £2,200 million investment programme.

The proposal to sell British Telecom goes beyond measures earlier this year to liberalize British telecommunications. Last October, the government passed legislation allowing private companies to supply equipment for attachment to the network in competition with British Telecom. Equipment is still awaiting approval. Earlier this year, the Mercury Consortium, a group of three private companies, was licensed to operate a new telecommunications network in competition with British Telecom. And shortly, Mr Jenkin promises a general licence permitting the use of BT and Mercury networks by suppliers of value-added or third party services.

The new bill will transform British Telecom into a public limited company and allow the sale of up to 51 per cent of the shares to the public. As soon as half the shares have been sold, the government will relinquish its control, allowing the company to borrow from shareholders and private markets. British Telecom's present status as a licensing authority will be transferred to the industry secretary acting through a newly-created Office of Telecommunications. Regulations — balancing the interests of those involved in the supply and use of telecommunication services — will be controlled by the new office. Licences to operate services will be issued, according to Mr Jenkin, only to those companies willing to fulfil their public duties by, for example, supplying uneconomic services to rural areas.

No doubt still smarting from the embarrassment of under-estimating the share price of Amersham International, sold off earlier this year, Mr Jenkin is as yet unwilling to hazard a guess at the value of British Telecom or the shares that will be on sale. Neither does he seem in any hurry to push the sale through. The legislation can be expected to be enacted by the end of next year, he says. But the sale of shares is not scheduled before the next election, which must occur before May 1984. The present government is clearly confident that it will have another term to run.

Judy Redfearn

Britain's nuclear power

PWRs hit snag

Mr Ron Anthony, recently appointed Chief Inspector of Nuclear Installations in Britain, wants to be counted on the side of the angels. Last week his Nuclear Installations Inspectorate (NII) published a report critical of several aspects of the "preconstruction safety report" for a British version of the Westinghouse pressurized water reactor (PWR), thus confounding environmentalists' fears that NII is in the pocket of the nuclear industry.

"As far as we're concerned, no-one could go too far in the matter of safety" said Mr Anthony last week, stressing that assessment of the Central Electricity Generating Board (CEGB)'s design would be continuous right up to the moment of operation. Next January, there will be a planning inquiry on the PWR, but even if the inquiry favoured the reactor, NII would still have the right to refuse a licence.

Is this unexpected opponent causing shudders in the nuclear industry? Not yet. Mr Anthony's inspectoral bark is judged to be worse than his bite. The director of CEGB, Sir Walter Marshall — nuclear physicist and passionate advocate of the PWR — said he was delighted that NII had flexed its muscles, while at the same time giving CEGB a pass mark on all the difficult issues (such as containment vessel design). Moreover, the NII report says frequently that a satisfactory and safe PWR design is "achievable", and that CEGB has only to satisfy NII on certain points.

These are many, and include "human factors" now known to have played a great part in the Three Mile Island accident. "In the preconstruction safety report [for the British PWR] there is only brief mention of the role of the operator in testing and maintenance, operating procedures, operator training, the control room and operator response to faults" says the NII report. "The various sections give little indication of intent to design and operate on good ergonomic principles." NII is not unduly worried, however: CEGB is considering the problem, the inspectorate says, and NII will have evidence of the CEGB conclusion before a licence is granted.

More substantial, in NII eyes, are five concluding points gathered together as "not yet satisfactory". These are:

- Hazards presented by fire, earthquake and aircraft crash.
- "Ballooning" of the fuel cladding.
- Steam generator tube integrity.
- The automatic reactor protection system, which is a completely new design.
- CEGB's software models of fault development.

The report also says that the possible consequences of severe accidents will be the subject of a separate CEGB submission and NII report.

Of all these, Sir Walter Marshall is most worried about ballooning of the fuel cladding, a phenomenon discovered by UK Atomic Energy Authority researchers, Sir Walter's former colleagues. The problem is that uranium fuel rods necessarily contain a small amount of helium and that if the surrounding coolant pressure suddenly drops, this gas can balloon out of the cladding and close off coolant flow completely. For this to happen, the cladding ductility — and hence fuel-rod temperature — has to be just right, and the pressure must not fall too fast (otherwise the cladding simply bursts, allowing coolant past the ragged edges). The combination of conditions is unlikely, but it requires only a small loss-of-coolant accident, said Sir Walter. Experiments are under way in Canada to measure precisely the conditions in which ballooning occurs, but Sir Walter "stakes his reputation" in predicting that the phenomenon will prove to be no substantial obstacle to reactor safety.

The automatic reactor protection system is the other, more substantial, doubt. Relying on modern microelectronics and computer control, this system would handle major faults for 30 minutes before an operator was allowed to touch the controls. NII has no objection to the principle, but remains to be satisfied that it will work. That will require six years of software analysis and testing, said Sir Walter last week. He will set up a team of 10–20 specialists to do the job.

0028-0836/82/290316-01$01.00

Whales' Waterloo

Science, it seems, has once again failed the sperm whale. Among other issues, the annual meeting of the International Whaling Commission (IWC), which convenes this week in Brighton, must decide on sperm whale catch limits. Quite how it will do so is not at all clear. The Scientific Committee of IWC, which met two weeks before the main commission, has, as last year, failed to make a recommendation.

Indecision continues to cast a cloud over the sperm whale. At a special meeting in March (*Nature* 1 April, p.383) the Scientific Committee, using the computer model developed by the International Institute of Environment and Development (IIED) and supported by all but the Japanese scientists, estimated the number of exploitable whales at around 200,000. The analysis indicated that even with a zero catch, stocks would continue to decline. The Japanese presented their own computer model and pushed for a minimum quota of 890. A decision on catch limits was deferred to this week's annual meeting.

The recent meeting of the Scientific Committee produced a few surprises. A majority of the committee agreed that the IIED model estimate of population size had been too optimistic and that the population continues to decline. The Japanese did not re-present their earlier model but put forward a modification of the IIED model indicating that earlier population estimates were low.

In view of the Japanese dissent, the Scientific Committee was unable to recommend a catch limit or to classify the stock. Because of the disagreement on the state of the sperm whale stock it is difficult to assess whether a catch of 890 could be sustained without taking a serious toll on the population. The buck has now been firmly passed back to the IWC delegates. A political trade-off must now be made. The sperm whale is not the species in greatest danger of extinction. With the conservationist countries determined to stand firm and press for a total ban, some clever manoeuvring is now called for if IWC is to avoid even greater schism.

Jane Wynn

Badger gassing

Ferrets stand in

The study which earlier in the month precipitated the British government's abandonment of the policy of gassing badgers appears to have provided the most detailed information so far of the mortality of ferrets exposed to hydrogen cyanide. A total of 177 female ferrets were exposed to hydrogen cyanide in the course of the study, but only four badgers were thus used because of their scarcity.

The issue of gassing badgers with cyanide has been contentious since 1975, when the Ministry of Agriculture, Fisheries and Food began gassing badgers suspected of being carriers of bovine tuberculosis. The practice was suspended towards the end of 1979 after complaints from conservationists and wildlife organizations that it was unnecessary, inhumane and ineffectual, but resumed in October 1980 after a report from Lord Zuckerman that confirmed that badgers can be reservoirs for bovine tuberculosis, a conclusion disputed by some conservationists.

The Zuckerman report on badgers also pointed to the lack of experimental evidence of the effects of cyanide on badgers, when the study commissioned by the agriculture ministry from the Chemical Defence Establishment at Porton Down (not to be confused with the now-civil microbiology establishment at the same place). The report of that study, by anonymous officials at the establishment, was published last week.

The first objective of the study was to establish a kind of dose–response relationship for mortality among ferrets, chosen as experimental animals on the recommendation of Lord Zuckerman. One of the defects of the study is that the sample of ferrets (obtained from a commercial supplier) appeared to consist of two groups differing in body weight. The animals were exposed in groups of three to various concentrations for periods of 1, 5 and 25 minutes. Nothing is said in the report of the age of the animals, which had nevertheless been bred especially for the study.

Eric Hoskins

The exposure of ferrets is measured as the product of the concentration of cyanide in the air and the time in minutes for which the ferrets breathed it. The ferret part of the study was used so as to estimate the likely lethal doses for badgers, fourteen times heavier than ferrets on the average, by means of the rule that the exposure required to produce a specified mortality is proportional to (body-weight)$^{0.7}$.

On this basis, the estimated exposures to cyanide needed to kill 90 per cent of badgers after times of 1, 5 and 25 minutes are 2,000, 5,000 and 5,500 mg min m^{-3} respectively. The report says that these "crude" estimates are supported by the experiments in which four badgers were exposed to cyanide gas. The only badger that died was exposed to 6,560 mg min m^{-3} for 17 minutes; the other three have been returned to the wildlife park from which they came.

The government's decision to abandon the use of cyanide against badgers has been prompted by the knowledge that concentrations of cyanide in the tunnels of badger setts rarely approaches that needed to kill them within minutes, if at all. Its problem now is whether it can devise an alternative humane way of killing badgers — and do so quickly. Conservation interests will be able to exploit a prolonged hiatus in the control programme to reopen the question of its necessity. The use of carbon monoxide and nerve gases as alternative methods of control was ruled out in the Zuckerman report as being respectively ineffectual and "too dangerous".

British academic industry

Prize incentives

"We realize that we're just a football. We're here to be kicked by both sides." Thus a spokesman for the British Technology Group (BTG) on the group's present interest — the marriage of industry and academic science to put high technology on the market. In its latest venture, an academic enterprise competition, BTG hopes to encourage academics to don the entrepreneurial cap. Last week, Patrick Jenkin, Secretary of State for Industry, handed out cheques totalling £230,000 to twelve winning entries.

The academic enterprise competition, originally sponsored by the National Research Development Corporation (now part of BTG), was open to science researchers from British institutions of higher education who had set up, or planned to set up, a business based on their research work. At the award ceremony, enthusiasm ran high. Sir Alastair Pilkington, chairman of the panel of five judges, declared "We would like to see a large number of academics become millionaires every year". Patrick Jenkin described the occasion as one of "unique importance". The competition was all about the partnership between education and industry and aimed to dispel the feeling that "somehow for an academic to go into industry is disreputable". He issued a warning that the government's position was firmly on the sidelines. Public funds were but the seeds of support.

Professor W.A. Gambling of the University of Southampton, whose company York Technology Ltd took the top prize of £50,000, agreed that if Britain is to "seize the juicy plum" and commercialize high technology, higher education must play its part. But he added that the main occupation of the academic remains teaching and research.

Although legislation has yet to be passed, the National Research Develop-

0028-0836/82/290317-02$01.00

ment Corporation and the National Enterprise Board were merged to form BTG in September 1981. A Universities Coordination Unit was set up to go on the road and seek out entrepreneurs in the academic world. Last week's competition has at least provided a market survey. BTG now knows that there are at least 118 groups, the number of entries in the competition, keen to set up business ventures based on academic research.

Electronics and information technology dominated the entries but engineering, medical equipment and biotechnology were strongly represented. More than a third of the entries came from research institutions in the south of the United Kingdom. York Technology Ltd, the winner, was set up in 1980 to market products for the optical communications industry. Its first product, a "preform profiler" which measures the refractive-index distribution in glass preforms from which long lengths of optical fibre are drawn, was invented and patented at the University of Southampton. So far, £250,000 worth of equipment has been sold, 80 per cent as exports.

BTG may inject further cash, up to £250,000, in some of the prize-winning companies. It hopes, however, that private industry will become more interested and step in to bridge the investment gap. The competition seems to have established that while academics' sights may not yet be set on making a million, there is no shortage of people willing to give it a try. **Jane Wynn**

Synthetic fuels

Support wanes

Washington

The "synfuel fever" that led Congress in 1980 to launch a 12-year, $88,000 million development plan seems to have lapsed into a synfuel coma. The US Synthetic Fuels Corporation, established by Congress to distribute the funds, is off to a slow start — several large privately-supported projects have recently collapsed and the economic projections of the profitability of synfuels are becoming bleaker.

Last week, the board of directors of the synfuels corporation continued at its measured pace, eliminating about half of the 35 proposals received in the second round of applications. The corporation has taken a very cautious course, so far selecting only two projects out of the first round and pledging to be "tough negotiators" in settling on the details of the government support for those. Chairman Edward Noble has also made clear that once the corporation has spent the $14,600 million already appropriated to it, there will be no more funds available.

Yet even this is more than synfuel supporters had expected from the Reagan Administration. According to the Democratic staff of the House fossil and synthetic fuels subcommittee, the Administration now appears "to support at least the concept". But John Sawhill, who was Secretary of Energy and, briefly, chairman of the synfuels corporation under President Carter, says that the corporation is doing "the minimum possible that will keep Congress off its back".

But critics of synfuel development say the industry's real problems go deeper than the policies of the synfuels corporation. Technological uncertainty, high risks and a declining world price of oil are formidable obstacles. Earlier this year, two large private projects collapsed, apparently for these reasons. Exxon, the world's largest corporation, pulled out of the Colony oil shale project in Colorado after the estimated construction costs doubled — to $6,000 million.

The Alsands oil sands project in Alberta, Canada, suffered a similar fate, almost simultaneously, when both Shell Canada and Gulf Canada pulled out. And the two projects that the synfuels corporation has chosen to support — the Breckinridge oil-from-coal project in Kentucky and the Hampshire Energy gasoline-from-coal project in Wyoming — are reported to be having trouble finding equity backers.

An industry source said that Exxon's main trouble with the Colony project was that artificially high oil prices had made what are basically "neanderthal" technologies seem attractive.

Meanwhile, other projects are continuing. Union Oil is reported to be more than half-way to completion on its $2,000 million, 10,000 barrel per day shale project in Colorado, and work is also progressing on the $2,100 million Great Plains coal-gasification plant in North Dakota. Exxon, in spite of the setback on the Colony project, is going ahead with a small direct coal liquefaction plant in Texas and a coal gasification project in the Netherlands.

The industry is not dead; but neither is it just hibernating, as some of its supporters claim, waiting for the next rise in oil prices. The change of plan by Exxon was clearly a blow; as one observer put it, "it was a shock to everyone that Exxon couldn't do everything".

A reevaluation of the long-term economics of synfuels is at the heart of the industry's sickness. The draft of an Office of Technology Assessment study reports that even with the large loan guarantees available from the synfuels corporation, investment in particular projects seems attractive "only if current capital cost estimates for synfuels plants are correct and there are no cost overruns. Most industry experts, however, consider the chances of cost overruns to be high."

Some economists have also begun to question the rationale behind synfuel development. Arthur Wright of the University of Connecticut doubts that even a credible supply of synfuels at a credible price would insulate the American economy from the effects of oil price rises. "Synfuels might reduce imports, but not the source of the instability", he says.

Britain is odd-man-out on 2,4,5-T

The European Commission is urging the Community's member states to take greater precautions to ensure that herbicides containing 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) do not contaminate food. In a surprising move, the Commission is recommending that the Council of Ministers adopt a directive forbidding the use of 2,4,5-T on cereals and woodlands when fruits and mushrooms are in season and in weedkillers for domestic use. The Commission is also recommending that the maximum permitted level of the toxic contaminant 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) be reduced immediately to 0.01 mg per kg of 2,4,5-T and later to 0.005 mg per kg when a method of control at such a low level is available.

The Commission's move may embarrass the British government, even though Britain, together with Belgium and West Germany, already operates the 0.01 mg per kg limit for TCDD in 2,4,5-T. The British Ministry of Agriculture has repeatedly given 2,4,5-T a clean bill of health provided that it is used as recommended. The ministry's view was challenged in 1980 by the National Union of Agricultural and Allied Workers (NUAAW) which claimed to have evidence of harm to individuals who had been in contact with 2,4,5-T. But the Advisory Committee on Pesticides, which the ministry asked to reply, saw little evidence to make it change its mind.

Thus, not surprisingly, NUAAW is greeting the Commission's move with enthusiasm while the agriculture ministry is more guarded, preferring to wait for the Council of Ministers' decision before responding to the Commission's recommendations.

The Commission's decision to move on the side of caution is the result of a review conducted in 1980 by its scientific committee for pesticides. Although that review found no evidence of direct harm from the proper use of herbicides containing 2,4,5-T, it nevertheless recommended lowering the level of TCDD in 2,4,5-T and greater precautions to minimize 2,4,5-T in food. Whether the Commission's recommendations become binding on EEC member states will depend on how they are greeted by the Council of Ministers. Whatever the outcome, however, Italy, the Netherlands, Denmark and West Germany will be unaffected. They have already banned use of the chemical as a herbicide.

0028-0836/82/290318-02$01.00

The industry's sorry state is compounded by Congress's loss of enthusiasm in the past two years. The 1980 Energy Security Act, which set up the government synfuels projects, also authorized spending on solar energy and conservation. With the dropping of all but the synfuels portion of the act, the coalition of environmentalists and oil-industry supporters that passed the act has fallen apart. A new anti-synfuels coalition, now made up of environmentalists and the much larger body of fiscal conservatives, is trying to destroy government synfuels support. So far, this coalition has had little success, but the days of government support for synfuels are surely numbered.

Stephen Budiansky

High-energy physics

Labour intensive

They have been playing musical chairs at CERN, the European Centre for Nuclear Research near Geneva. Last week there were six proposed experiments for LEP, the large electron-positron collider due to start up at the end of 1987. Now there are four, after a preliminary examination of the proposals gave a cautious thumbs down to the other two*.

But the number of physicists remains the same, so that the 850 scientists involved in all six proposals will attempt to regroup to find jobs for all, in a process that CERN dubs "optimalization". Final approval of the arrangements will be given at a research board meeting in November.

The scale of the LEP collaborations is thus going to be vast, far bigger than foreseen only two years ago. Then, the European Committee for Future Accelerators (ECFA), in a report on the future employment of physicists in Europe, predicted collaborations averaging only 75 physicists on each of six LEP experiments. Now the figures seem likely to reach 200 on each of four experiments. Rutherford, where is you string and sealing wax now?

Dr Jack Mulvey of the University of Oxford, who produced the ECFA report, said this week that he thought the main problem was going to be project management. But particle physicists had shown a remarkable ability to adapt to new conditions. "We've realized that it takes an enormous effort to get these big experiments on the floor", he said, and that large collaborations are necessary.

The LEP collaborations will also need to be big to spread costs — for this time CERN is not following its usual policy of offering about half the capital cost of the equipment, but will restrict itself to one-fifth. Since the total sum for the four experiments is some £75 million, the matter is not negligible.

The other problem is whether there will be enough jobs for the 2,000 or so particle physicists in Europe when LEP is built. Mulvey thinks there will, as the ECFA report deemed the situation satisfactory with only 450 researchers at LEP. Although the intersecting storage rings at CERN will be closed down, and there will be less work at the Super-Proton Synchrotron, there will be enough to do at the proton-antiproton collider, at the low energy antiproton ring (LEAR) and at other European laboratories such as the Deutsches Elektronen-Synchrotron in Hamburg, the ECFA report concluded.

Although "four experiments" sounds rather modest, LEP should be an excellent physics factory, provided that the particle called the neutral intermediate vector boson (Z°) exists. LEP is designed to be tunable to this resonance, which is the predicted mediating particle of the electroweak interaction. If the resonance is not there, however, or if it proves difficult to tune to it, there will no doubt be 850 unhappy physicists.

Robert Walgate

Franco-Soviet space flight

Some hitches

The visit of "*spacionaute*" Jean-Loup Chrétien to the Salyut-7 space station last month has introduced an unprecedented degree of candour into the reporting of Soviet space flights. Usually, cosmonauts' post-flight press conferences gloss over technical hitches and report as "satisfactorily accomplished" even those missions that were quite obviously curtailed.

The Soviet planners clearly accepted that the presence of a Westerner would entail more candid reporting, and a few days before the launch even admitted that Salyut-7 suffered unexpected attitude changes that had had to be corrected before link-up. Attitude, however, continued to give trouble throughout the flight, both aboard the Soyuz-T transport craft and on Salyut-7 itself.

According to Chrétien, the on-board computer of Soyuz-T suddenly ceased its automatic plotting just as the craft was approaching the space station at speed. This left Soyuz-T in a rolling motion, from which the crew of three had to effect a manual docking. This, Chrétien later explained on French radio, was not a breakdown — but it came at a critical moment when the crew could not even see the space station.

Orientation problems continued on board Salyut. The French contribution to the programme included high-sensitivity photography of the Earth's atmosphere and the interplanetary environment in the visible and near-infrared range. Another experiment was to photograph very weak light sources, from noctilucent clouds to distant galaxies. Both experiments required both darkness and a high degree of stability.

According to the crew commander, Vladimir Dzhanibekov, both these factors caused difficulty. The cosmonauts repeatedly lost their equipment (cameras, cassettes and so on) in the dark. Worse, flare from the thruster rockets necessary to maintain stability interfered with the lengthy exposures necessary. Dzhabenov said that such a possibility had never occurred to them before the launch.

Similar problems seem also to have arisen with the various physiological experiments. The crew is said not to have been able to think them through before launch and therefore to have had to "carry out additional training" in space. This seems remarkable — the focus of the medical programme, the French "echography" project, a Doppler measurement of blood-flow in the arteries leading to the brain, was intended to compare cadiovascular function before, during and after the flight. The crew should therefore have been familiar with the apparatus long before take-off.

The apparent lack of preparation may perhaps be due to the international nature of the flight which, contrary to Soviet practice, tied the launch to a pre-announced date.

CORRESPONDENCE

Nuclear dangers

SIR — Nils Ove Bielsten (*Nature* 25 March, p.284) claims on the basis of "fact" that nuclear power plants are safer than hydroelectric, causing far fewer fatal casualties (a rather dubious claim considering comparative risk analysis), "not a single one occurring to people outside the plants (except possibly in accidents due to construction work traffic)". Yet again the impeccable record of nuclear power is invoked and compared with other sources of energy.

Is it not time to recognize and admit to the dangers of the whole chain of supply of nuclear fuel from mining to its eventual and undecided disposal? Uranium mines where studies have been possible, including some in the United States, have recorded mortality rates between 50 and 100 per cent. Surrounding native American communities also suffer casualties with the additional destruction of their environment and traditional livelihoods, especially painful for people with a traditional respect for the health of the Earth. I believe that it is time for a wider perspective to be taken on large scale projects such as this. Debate over social cost-benefit analyses, environmental impact assessments and technology assessments, which are prone to value judgements, does not negate their usefulness.

The casualties of Britain's earlier plutonium/electricity plants are also becoming apparent and substantial sums have been paid in compensation for workers' deaths.

The economics of nuclear plants are not quite as simple as Mr Bielsten would have us believe either. Left to the electric utilities, as he approves, we find that in the United States no new plants have been ordered for years and several have been cancelled. Plant cost escalations have run up crippling debts for communities and have sent utilities to the federal government for help. In the United Kingdom, it is now suggested that Scottish electricity consumers are paying the price for an unnecessary plant at Torness whose claimed "robust economic case" rests on a possible four-year period when, if coal plants are closed early, it may be useful. Government and independent investigations cast some doubt on even this value to consumers now that costs, need and forecasts are at last being debated.

The writer claims that "nuclear power is the environmentally soundest way of producing the energy that we cannot do without". Yet the people of Sweden have voted not to build any further plants beyond those already started. Their closure is already decided and a transition has been embarked on for a programme of energy efficient development — ending waste to liberate extra available energy. Renewable energy technologies are increasingly the source of new space heating needs and other requirements.

This approach, and energy efficient developments in the United States, demonstrate the value of demand management as a crucial aspect of energy planning.

Finally, Mr Bielsten's reference to possible benefits of mutation in the population is worrying. If it is a serious point then further debate is necessary.

MARTIN S. FODOR

Milton Keynes, UK

Complicating SI

SIR — Like J.A. Nicoll (*Nature* 10 June, p.450) and probably many others I have considered a simplified notation for physical quantities in terms of SI units.

The appropriate unit is automatically implied by the quantity that must necessarily be specified. Thus the statement that a force is 12 should denote by the absence of units that the SI system is employed and that the force is thus 12 m kg s^{-2} or 12 N. Whenever SI is not utilized units must continue to be provided as in 0.237 lb ft min^{-2}. The convenience of omitting units might thus speed the general adoption of SI.

Prefixes (kilo etc.) are not merely clumsy but they conflict with a principal virtue of SI which is coherence. The nuisance of large or small numbers could of course be lessened by the method commonly practised in computer printouts where 67,000 is written as 6.7 E + 4. However, a simpler notation might be 4;6.7 which specifies the numbers as read from left to right in increasing detail. The semicolon indicates that the number to the left is the power of ten and the period between 6 and the 7 might in time be dropped by convention. Such numbers are subject to rather obvious and simple rules in algebraic procedures.

In this notation the speed of light is 10;2.99776 and the electron rest mass -31;9.109. For the rather unusual case where a physical quantity has a negative value some further symbolism would be required. Perhaps one might adopt the method used by accountants to indicate net loss rather than net profit. In this case the absolute zero temperature on the centigrade scale would be (-2;2.73) C.

Here the unit would have to be provided since the Kelvin scale can also be employed. Amongst other virtues the latter does not have negative values and one would have $-\infty$;0. Which seems a bit odd but could of course also be written conventionally as 0.

German universities

SIR — Thank you for the splendid review on "Science in West Germany", which was published in *Nature* on 27 May. There are, however, some additional points on the present situation of German universities which I would like to highlight.

The statement that government support of science will decrease by 2 per cent in real terms in 1982 is not quite true for the universities. For instance the universities in Nordrhein-Westfalen are facing severe budget cuts which give them only 55 per cent of the 1980 budget. For some institutes in the natural sciences this is less money than they had in 1975, and student numbers have risen by some 50 per cent since; readers of *Nature* will know themselves how much they had to spend on lab-ware and chemicals in the meantime.

Another point is that the measures taken to reform German universities are in fact cutting the numbers of teaching and research personnel at the universities. Only 50 per cent of the young scientists who pursued a university career and "habilitated" themselves in recent years are eligible for a university job in the new frame law-university structure. The Nordrhein-Westfalen measures to concentrate university studies especially in teacher training, which date from March 1982 and were covered in the *Nature* review, are said to last for at least 5 years in order to transform university jobs into jobs at the Aachen *Klinikum;* at the end of these 5 years the numbers of personnel in the physics and biology departments at Bonn University will have been reduced by 50 per cent.

Since nobody is talking about student number reductions, please add all this up: what you come out with is a catastrophe. Already experimental work for diploma and doctorate theses in biology often is not financed by the universities, but by money from Deutsche Forschungsgemeinschaft (DFG). Although nobody likes to talk about it aloud, DFG funds are also being spent for teaching jobs and so on. Teaching is severely affected: at Bonn the biology department will have to cut lab courses by one third, the chemistry department is seriously thinking about closing down its central chemicals store. All this makes orderly studies and research impossible. The outlook for Germany's universities is very, very grim.

THOMAS SIMON

Bonn, West Germany

Living in the past?

SIR — It would be unfortunate if the pungent style of S. Blinkhorn's review of *The Mismeasures of Man* by S. J. Gould, (*Nature* 8 April, p.506) should weaken the force of his criticism. Like Blinkhorn I think there is much to object to in this book and, for T. J. M. Schopf (*Nature* 13 May, p.98), I would like to document a few of its substantive faults.

Although he has references as recent as 1979, Gould ignores major studies and references of the 1970s relevant to the topics he is considering in depth. Consequently, the reader will not learn from Gould's book that most geneticists are *not* "biological determinists"[1,2] nor that modern studies of heredity of cognitive abilities do *not* rely on a single (mystical) measure of intelligence[3].

Gould devoted 83 pages to the demolition of nineteenth century claims for an association between cranial capacity and human intelligence and the casual reader undoubtedly will think that he has thoroughly covered this topic. But he omits a critical 1974 review of the subject by Van Valen[4] which concludes that there probably really is a small positive correlation. Interestingly, Van Valen's conclusion is also ignored by Lewontin (discussing the same subject) in his favourable review[5] of Gould's book although Van Valen thanks Lewontin for comments (as does Gould).

Gould documents in great detail some blatant errors of the past but, by not coming up to the present, misleadingly implies that it is no different from the past. One would like to know why.

NEWS AND VIEWS

New branches for old roots

from Barry Cox

THE battle seems now to have been joined in earnest. Waving their branching weapons of attack, some of the cladists are now assaulting even the most fundamental roots of the systems of relationship that the traditional evolutionary morphologists have developed. After the skirmish over the tetrapod-origin outpost, in which Rosen *et al.* (*Bull. Am. Mus. nat. Hist.* **167**, 159; 1981) suggested that lungfishes rather than rhipidistians were closest to tetrapod ancestry, Gardiner has now used cladistic techniques to transform the whole system of tetrapod classification (*Zool. J. Linn. Soc.* **74**, 207; 1982).

Gardiner's method is first to return to the criteria given by nineteenth century anatomists in their analyses of relationship of the major tetrapod groups. Thus he concludes that "the denial of any immediate relationship between the mammals and the other great homotherm (*sic*) group, the birds, was based on no more than three characters; the form of the heart, aortic arches and occipital condyle". These three characters he swiftly demolishes (in about a page of text), and immediately moves on to list a number of characteristics of homoiothermy and of the central nervous system that appear to link mammals and birds as sister-groups. He relates to these two, in order of increasing distance, the crocodiles, chelonians and lepidosaurs. In all these discussions, palaeontology is ignored and only the characteristics of living animals are used. Into the resulting classification, Gardiner then fits a few fossil groups, such as the pterosaurs (a sister-group of birds), dinosaurs in Owen's original sense (sisters to crocodiles), the cynodonts (far divorced from the mammals), the dicynodonts (sister-group to the chelonians) and the pelycosaurs (completely separated from the previous two groups). The results are so different from those that also incorporate palaeontological data that a headlong collision is inevitable, for there can be no minor shifting of viewpoints or emphasis that could lead to a reconciliation or synthesis.

Gardiner's methods can be illustrated particularly well in his treatment of the Synapsida, the splitting of which into three separate groups (pelycosaurs, dicynodonts and cynodonts) is, to a palaeontologist, one of the most revolutionary aspects of his work. Basically, he rejects previously established relationships if he can quote other workers to the contrary and can show that some members of any other group also share some of the features previously thought to support the accepted relationship. So "as long ago as 1926 Berg wrote that the mutual similarities between mammals and (advanced synapsids) were probably due to convergence" and "despite the fact that fenestrae might have arisen independently (as they have done within the Chelonia . . . and Amphibia . . .), today's unquestioned doctrine is that the Synapsida include the mammal's closest relatives".

Gardiner also underestimates the modern palaeontological evidence by restricting himself to out-dated authors; is it really true of the pelycosaurs that "Their claim to Synapsid relationship apparently rests on Cope's (1884) insistence on their closeness to mammals and the possession of a lateral temporal fenestra"? Reisz, himself a cladist, states that "The pelycosaurs, together with their descendants, form a natural group and possess such derived characters as broad anteriorly tilted occipital plate . . . reduced post-temporal fenestrae, single median post-parietal, and septomaxilla composed of a broad base and a dorsal process" (*Spec. Vol. Syst. Ass.* **15**, 553; 1980). The relationships of pelycosaurs to both dicynodonts and cynodonts (and also to other therapsid and theriodont groups) is also suggested by the fact that all these groups share with sphenacodontid pelycosaurs the synapomorphic feature of a reflected lamina on the angular bone of the lower jaw. All, except the turtle-beaked dicynodonts, also share in having a heterodont dentition.

The cynodonts, like some other advanced synapsids, show a progressive reduction of the post-canine dentition and of the post-dentary bones of the lower jaw, with the mammalian type of squamosal-dentary jaw articulation having evolved in a few forms, and various approaches to the mammalian condition in the secondary palate, dentition, limbs and girdles. Gardiner nevertheless dismisses any relationship between cynodonts and mammals because an examination of the British Museum (Natural History) specimens of the cynodont *Thrinaxodon* "failed to reveal a single mammalian synapomorphy" and, for example, showed that *Thrinaxodon* was not particularly mammalian in its tooth-replacement and braincase. But it is such later, mid-late Triassic cynodonts as ***Probainognathus*** and the trithelodonts that are thought to be close to the origin of mammals, and these do show far more mammalian conditions of the teeth and braincase.

It seems perverse to reject these complex similarities merely because our extensive knowledge of the osteology of both recent and fossil tetrapods reveals isolated instances where temporal fenestrae have evolved independently (and, in any case, the chelonian openings that Gardiner quotes are emarginations, not fenestrae). We have no such systematic knowledge of the soft-part anatomy, physiology or biochemistry that make up the 17 characters that Gardiner lists to support his contention that birds and mammals are closely related sister-groups. As Szalay (*Am. Zool.* **21**, 37; 1981) has commented: "I believe that at the very heart of the post-Hennigean cladistic approach to phylogeny reconstruction lies the implicit neglect for biological and functional scrutiny of the characters employed. As a result of this attitude the postulated homologies chosen (the units on which phylogenies are based) are not biologically investigated and therefore the chances of discovering whether these features are unique or parallel or convergent acquisitions, or whether they represent a pattern commonly attained by distant lineages because of epigenetic factors, or because they are rooted in a common heritage, weakens the very foundations of such analyses. In other words, character analysis commonly practised in cladistics is really a semantically masqued enumeration of characters without attempts to analyse and weight them".

Gardiner's suggestions are so completely at odds with the palaeontological record that some of Panchen's observations, in an incisive criticism of the cladistic method published in the same volume as Gardiner's work (*Zool. J. Linn. Soc.* **74**, 207; 1982), seem particularly relevant. "The first obvious fault of cladism in general is perhaps a temperamental and, one may hope, a temporary one. This is the temptation to produce new and revolutionary groupings of organisms, or to resurrect old and discredited ones, just to demonstrate that cladism is getting results." □

Chaos, randomness and dimension

from T. Geisel

CHAOS and randomness are ubiquitous. In many scientific disciplines, random time series are obtained from an experiment and analysed into their power spectra. Often enough, the irregular motion of a system will have been produced by an external noise source. On the other hand, irregular motion and irregular time series may also be self-generated by a purely deterministic system. In the latter situation the term 'chaos' is used and, in a state space description, its dynamics are often governed by strange-looking topological objects called 'strange attractors'. As the scientific community is becoming aware of this phenomenon, observations of irregular behaviour that previously might have been ignored are attracting attention. The following questions then arise: given only the irregular time series, is it possible to tell whether it is due to chaos in the above sense, that is, does it have intrinsic properties which allow such a decision? Is it even possible to reconstruct the strange attractor, the ID card of the system, from the time series? These questions have been addressed in several recent papers which are reviewed in this article.

When irregularity is due to thermal fluctuations in physical systems, a large number (10^{23}) of particles and degrees of freedom are involved, which make the measurements look noisy. In brownian motion, for example, the irregular motion of a heavy test particle only reflects the irregular dynamics of 10^{23} molecules in the surrounding liquid. The terms 'randomness' and 'noise' describe such situations. 'Chaos', in contrast, is reserved for an irregularity that is self-generated by a deterministic system with few degrees of freedom in the absence of external fluctuating forces. Simple examples are driven anharmonic oscillators[1], where the phase space is three dimensional, consisting of position x, velocity v and the phase ψ of the driving force. In an undriven damped harmonic oscillator, the motion would asymptotically settle down at $x=0$, $v=0$. This point is called an attractor because any initial condition x_0, v_0 in a given area of phase space would lead to this point. The dimension is thereby shrinking from two to zero. For chaotic systems which are dissipative, attractors called strange attractors[2,3] may occur. These are asymptotic limit sets in phase space which also have lower dimension than the phase space and which have an additional property: the motion on the attractor is characterized by an exponential divergence of neighbouring states in some direction. This sensitive dependence on initial conditions is the cause for their strange appearance. It also practically prevents long-term predictions since the initial conditions are usually not known exactly. The sensitive dependence and the degree of unpredictability are measured by a variable called a Lyapunov exponent.

Strange attractors may not only occur in systems with few degrees of freedom but also in systems where, *a priori*, the dimension of phase space is high or infinite. An example is provided by turbulence in fluids and other systems that can be described by partial differential equations. Due to the presence of dissipation (damping) the motion in multidimensional phase space may, with time, settle down on a strange attractor which acts like a low-dimensional trap. The motion can then be described by a few variables in phase space. If the topology of the strange attractor is known, the dynamics of the entire system is known. This explains the dominating role of low-dimensional strange attractors for the chaotic dynamics of systems that may have infinite dimensions. Due to the sensitive dependence on initial conditions, these attractors have a complex structure similar to a Cantor set. The fractal dimension[4,5] can be used to characterize their spatial organization. In contrast to the topological dimension, this number may be non-integral, reflecting the topological complexity.

When an irregular time series is observed in an experiment one may ask whether the irregularity is due to chaos or to randomness as distinguished above. When little is known about the system, one can only hope that the time series possesses intrinsic properties which make this distinction possible. Power spectral analysis, which is usually applied, is of little help but other techniques have recently been proposed. They can be used to determine the dimension of the underlying dynamics and the fractal dimension of strange attractors. It is even possible to reconstruct the strange attractors.

One procedure has been proposed by the Santa Cruz Dynamical Systems Collective (J.P. Crutchfield, J.D. Farmer, N.H. Packard and R.S. Shaw). They propose to use the observed signal $x(t)$ and its successive derivatives $\dot{x}(t)$, $\ddot{x}(t)$, . . . as variables spanning the subspace of phase space to be reconstructed[6]. The procedure has been applied successfully to a dynamical system due to O.E. Rössler. It cannot be applied when the time series is not detailed enough to determine the derivatives. Another procedure, suggested by D. Ruelle (personal communication), consists of using the signal $x(t)$ and delayed signals $x(t-\tau)$, $x(t-2\tau)$. . . . to span the phase space reconstruction. F. Takens[7] has given a formal justification of these procedures in terms of the Whitney embedding theorem.

Roughly speaking, the dimension is determined if, with increasing dimension, the objects produced by the motion start

100 years ago

THE NEW AFRICAN EXPEDITION

It is now understood to be quite settled that a new African exploring expedition will start next year. The Royal Geographical Society have, as might have been expected, taken the opportunity of Mr. Joseph Thomson's return from the completion of his engagement to the Sultan of Zanzibar to obtain his services as leader, and it is certain that no better selection could have been made.

Mr. Thomson will leave England in the Spring of 1883, and proceed to Zanzibar to organise the expedition. From Mombas, a port on the East African coast, to the north of Zanzibar, he will direct his course straight to Kilimandjaro, and do his best to explore the snowy ranges of this celebrated mountain, which but one European has as yet ever reached. Passing across the waterparting he will then descend through an entirely unknown country to the eastern shore of Lake Victoria Nyanza, and return to the coast by a more northern route, in the course of which it is hoped he may be able to visit Lake Baringo and Mount Kenia — another peak known to run far above the snow-level, but concerning which further details would be very desirable.

As a mere geographical expedition it will be thus seen that the proposed route will be one of great interest, embracing, as it does, the transit through much utterly unknown country, and the exploration of two mysterious snow-crowned mountains, which, according to the usual view of the conformation of the African Continent, appear to be quite out of place in the districts in which they are situated. But still more interesting problems will be solved, if steps are taken to investigate the unknown fauna and flora of Kilimandjaro and Kenia.

GEOGRAPHICAL NOTES

Lieut. Giraud has sailed from Marseilles for Zanzibar, as leader of a French expedition which proposes to take up African exploration where Livingstone laid it down with his life on the south shore of Lake Bangweolo. Lieut. Giraud proposes to go either direct west to Lake Tanganyika, or, more probably, by the north shore of Lake Nyassa, to the Chambeze River. This he will follow to its outlet in Lake Bangweolo, which he proposes to circumnavigate he will then attempt, in canoes, to sail down the Luababa-Congo, to its mouth in the Atlantic Ocean. This is an ambitious programme; and every one interested in African exploration will wish the expedition complete success.

From *Nature* **26**, 304 & 309, 27 July, 1881.

0028-0836/82/290322-02$01.00

making sense. More systematic techniques, however, are now available. The Dynamical Systems Collective uses linear regression locally to fit the data to points, planes or higher-dimensional hyperplanes[5]. The goodness of the fit is determined by χ^2, the sum of the squared deviations divided by the dimension. When the dimension closest to the fractal dimension is reached, χ^2 drops sharply. In the example of the Rössler system, a drop by a factor of one million was found for the best fit. Once the strange attractor has been reconstructed, the fractal dimension may be determined according to its definition[5]. Techniques to determine the fractal dimension and another measure of chaos, the topological entropy, have been described by F. Takens[7]. The relationship between the fractal dimension and the Lyapunov exponents has been investigated by P. Frederickson *et al.*[8].

Procedures which are able to distinguish between chaos and randomness are also suggested in an article by J. Guckenheimer published in this issue of *Nature* (p.358). These procedures are based on the assumption that randomness means unpredictability of the short-term evolution of a system. Chaos, on the other hand, is characterized by an exponential divergence of neighbouring states in phase space. This brings about only a long-term unpredictability of the system. Consequently procedures are constructed that verify exponential divergence of neighbouring states in the reconstructed phase space. Exponential divergence has also been investigated in terms of the Lyapunov exponent by R.S. Shaw for a chemical reaction system[9].

The methods outlined here have been applied successfully in real experimental situations. Strange attractors have been reconstructed for chaotic chemical reactions by J.C. Roux *et al.*[10,11] by using the time series of the concentration of a single chemical species — the phase space may in principle consist of at least the concentrations of all chemical species involved (about 25). D. Farmer *et al.*[12] have recently used a phase space reconstruction for a baroclinic flow experiment. In addition, they have been able to determine quasi-one-dimensional Poincaré return maps. R.S. Shaw *et al.*[13] have studied the irregular dripping of a tap and derived one- and two-dimensional return maps and topological and metric entropies from their measurements. ☐

Do mitochondria share enzymes with the rest of the cell?

from Thomas Fox

In a rough way, the matrix of mitochondria can be thought of as a cell cytoplasm containing a chromosome, a transcription and translation apparatus, and a number of metabolically important soluble enzymes. The peculiar thing, of course, is that much of this — for reasons that are unknown — apparently duplicates functions present in the real cell cytoplasm and the nucleus. It has seemed, however, that in no case does the same protein species function both inside and outside the mitochondrial matrix. Even though virtually all of the proteins present in the matrix are coded by nuclear genes, the matrix proteins studied so far have been found to be biochemically distinguishable from their functional analogues outside the mitochondria. A new report from Hopper *et al.* (*Cell* **28**, 543; 1982) now provides evidence that this may not always be the case. Work on two yeast mutants that affect tRNA methylation suggests that these functions are indeed shared by mitochondria and their gracious hosts.

The nuclear mutations, *trm1* and *trm2*, cause the absence of tRNA (guanosine-N^2, N^2) dimethyltransferase and tRNA (uridine-5)methyltransferase activities respectively. This was clearly demonstrated by examining HPLC elution profiles of ribonucleosides derived from digests of whole-cell tRNA preparations: $\mathrm{m}^2_2\mathrm{G}$ is specifically absent from the tRNA of the *trm1* mutant, while $\mathrm{m}^5\mathrm{U}$ is specifically absent from the tRNA of the *trm2* mutant. The modification of those tRNAs encoded and transcribed within mitochondria was examined by preparing tRNA from well-washed, isolated organelles, digested and analysed by HPLC. What was striking was that the purified mitochondrial tRNAs from wild type contained both methylated nucleosides, but $\mathrm{m}^2_2\mathrm{G}$ and $\mathrm{m}^5\mathrm{U}$ were specifically lacking in the mitochondrial tRNA from the *trm1* and *trm2* mutants respectively. Thus, the phenotype of these mutants is the same at the level of whole-cell (primarily cytoplasmic) tRNA and mitochondrial tRNA. On the face of it, it appears that for both modifications, the same (or similarly regulated) enzyme activities function inside and outside the mitochondria. (One assumes that the tRNAs do not leave the matrix to be modified and then return.)

It is dangerous to jump from the fact that a mutation affects an enzyme activity inside and outside the mitochondria to the conclusion that the mutation is in a gene coding both enzymes, without examining the enzymes themselves. Studies by Gross and co-workers on the *LEU5* locus in *Neurospora crassa* have shown that a mutation there leads to the production of an altered cytoplasmic leucyl-tRNA synthetase and to the virtual lack of mitochondrial leucyl-tRNA synthetase. Both phenotypes co-revert, indicating that they are the result of a single mutation. Furthermore, the genetic determinant for a naturally occurring electrophoretic variant of the mitochondrial enzyme also maps to the LEU5 region, indicating that structural gene information for both enzymes is in the same place (Beauchamp *et al. Proc. natn. Acad. Sci. U.S.A.* **74**, 1172; 1977). However, they could find no immunological cross-reactivity between the cytoplasmic and mitochondrial enzymes leading them to propose two tightly linked or overlapping genes for these two enzymes. Since the lack of immunological cross-reactivity may not be the most reliable indication that two proteins are unrelated, one should not yet rule out the possibility that a single gene codes for two, perhaps differently modified, leucyl-tRNA synthetases in *N. crassa*. However, in the case of the *trm1* and *trm2* mutations of yeast, the possibility of distinct but tightly linked and co-regulated genes for tRNA methylases should probably not be dismissed either.

A single gene, with two possible modes of transcription and translation, could clearly code for two similar proteins that end up on opposite sides of a membrane, as has been shown by analysis of a yeast gene that codes for both intracellular and secreted invertase (Perlman and Halvorson *Cell* **25**, 525; 1981; Carlson and Botstein *Cell* **28**, 145; 1982). It seems quite possible that such a mechanism also plays a part in specifying some proteins inside and outside the mitochondrial matrix. Clearly, an examination of the *TRM1* and *TRM2* genes of yeast and the *LEU5* gene of *N. crassa*, as well as the proteins they encode, will prove very enlightening. ☐

Bone in the cartilaginous fishes

from Brian Hall

THE recent documentation by Peignoux-Deville *et al.*[1,2] of bone in the vertebrae of the backbone of the dogfish, *Scyliorhinous canicula*, a member of the cartilaginous fishes (Chondrichthyes), has important implications for biology because sharks and rays are grouped together as cartilaginous fishes on the basis of the presence of a cartilaginous skeleton in the adult and the absence of bone from any stage of the life cycle. In other vertebrates, such as man or the bony fishes, most of the cartilage of the embryo is replaced by bone in the adult.

Cartilage and bone are the two major skeletal tissues. The long debate in evolutionary circles over whether cartilage or bone arose first during vertebrate evolution resulted in classifications of the vertebrates that had cartilaginous fishes either on the main evolutionary line as the ancestors of all other fishes and amphibians, if you believed that bone arose late in vertebrate evolution, or as a side branch, if you believed that bone arose early[3].

Peignoux-Deville *et al.* examined vertebrae of the dogfish using X-ray analysis, labelling with tetracycline (a calcium-seeking fluorescent drug) and transmission electron microscopy. The upper halves (neural arches) of the vertebrae were found to consist of large-celled cartilage overlain by a layer of lamellar bone containing bone-forming cells (osteocytes). The bone was calcified, as confirmed by the uptake of tetracycline and by the presence of calcium phosphate (apatite) crystals. Average mineralization (1g mineral per cm^3 of bone) was the same in the cartilaginous and bony portions of the vertebrae. The association of the bone with the underlying large-celled cartilage suggests that the cartilage may have induced the bone to form in the same way as occurs in higher vertebrates[4]. Mutants are known in which cartilage fails to become large-celled (for example, *talpid* in the chick, *brachypod* in the mouse), with the consequence that bone fails to form around the cartilage. Cartilaginous fishes appear to use the same developmental mechanism to form bone. The cartilage of higher vertebrates also contains canals which both provide cells for centres of bone formation deep within cartilage and allow nutrients to reach the deeper recesses of cartilage, a tissue which lacks blood vessels. Hoenig and Walsh[5] examined vertebrae from 16 species of sharks and found that all had canals containing blood vessels and immature cartilage cells. They ruled out any bone-forming (osteogenic) function for these canals .... "the osteogenic function cannot apply to Elasmobranch vertebrae", following instead the traditional view that sharks lack bone. A closer examination of these vertebrae is clearly now required.

Previous studies had hinted at the presence of bone in the endoskeletons of sharks and definitely showed it to be present in the hard denticles which are embedded in the skin and at the base of the teeth[6-11]. The X-ray diffraction pattern of shark vertebrae is also identical to that obtained from bone[12], and this and the presence of the canals should encourage a closer examination of shark vertebrae. *Ornithoprion hertwigi*, a fossil shark from the Permian period, had a thick layer of bone around its lower jaw[13]. The presence of bone in both the jaw and the vertebrae is of especial interest as much of the head skeleton is derived from the neural crest[4,14], while vertebrae are mesodermal in origin. Sharks have retained bone-forming potential in cells with both of these embryological origins. Bone formation in cells on the surface of the vertebrae is presumably activated by association with underlying large-celled cartilage while cranial neural crest-derived cells are presumably activated by interaction with epithelia, as happens in other vertebrates[14].

The existence of bone in these sharks explains the previously paradoxical presence of the hormone calcitonin, which acts on bone to regulate calcium metabolism. The presence of bone also highlights the chanelling of thinking which follows the classification of a group of animal on the basis of the presence of one, albeit major, feature and the lack of another. Because the Chondrichthyes are classified as having a cartilaginous skeleton and lacking bone, we automatically think that they are incapable of forming bone. This lead to the spurious classifications of vertebrates mentioned earlier, to the conclusion that no feature (canals, calcitonin) could have anything to do with bone or bone formation, that the cartilaginous fishes have 'lost out' in evolution, not having the potential for growth, mineral metabolism and structural support possessed by their bony cousins, and that any suggestion of the presence of bone must be spurious for cartilaginous fishes lack bone. The simple observation of the presence of a tissue in one region of one species opens up many roads for future travel. □

Hipparcos: space-age astrometry

from A.M. Cruise

THE measurement and cataloguing of stellar positions is one of the oldest branches of science and the results, gathered over the centuries, have been crucial in the formulation of our present concept of the scale and structure of the Universe. But astrometry is hardwork. To achieve a precision very much better than the arc second resolution of ground-based optical telescopes in a homogeneous manner over the whole sky seems impossible, with present instruments at least. It is no wonder then that astrometry has fallen from the front ranks of astronomical science, and spectroscopy and theoretical astrophysics have gained favour. Nevertheless, astrometry has some simple but profound truths to tell that are fundamental to the development of all branches of astronomy. By choosing the space astrometry mission 'Hipparcos', scheduled for launch in late 1986, the European Space Agency will transform many branches of astronomy and astrophysics.

The astrometric observations made from Hipparcos are hoped to have a precision of one or two milliarc seconds — one hundred to a thousand times better than is currently available for most stars. Such accuracy will allow both radio VLBI measurements and optical results to be specified in a consistent coordinate system.

Increased precision is not the only attribute of the Hipparcos catalogue. The instruments scanning sequence will allow observation of the whole celestial sphere during the two and a half year mission. About 1000,000 stars will be measured, including all stars down to ninth magnitude, and careful selection will ensure that there are always two or three

A.M. Cruise is at the Mullard Space Science Laboratory, University College London, Holmbury St Mary, Dorking, Surrey RH5 6NT.

0028-0836/82/290324-02$01.00

Hipparcos stars in each square degree of sky. A convenient, homogeneous coordinate grid of high precision that covers the whole sky will thus be created. In addition, the Space Telescope will be able to determine the position of some extragalactic objects with respect to Hipparcos stars and so link the new coordinate system to an inertial frame.

The increase in precision gained from Hipparcos will allow the absolute determination, by trigonometric parallax, of distances 10–20 times greater than at present. It is the absolute nature of the method which is of overwhelming importance. All the overlapping cosmic distance scales which span the observable Universe ultimately depend on measurements of the distance to the Hyades cluster which is just close enough to show measurable angular motion in ground based telescopes. Calibration of the absolute luminosity of various stellar distance indicators in the Hyades provides the means by which apparent luminosities of very distant objects can be used to determine their distance.

Not only will Hipparcos improve on the absolute distance measurement for the Hyades and so reduce the statistical error on all cosmic distance scales but more important, the absolute distance of five clusters other than the Hyades will be measured. The calibration of distance indicators can then be scrutinized for dependences on metallicity and other factors that might vary from cluster to cluster. Hipparcos will also increase the number of stars accessible to direct distance measurement by a factor of about 1,000 and absolute luminosity measurements over a much wider range of stellar temperature will be made possible.

The accuracy of measurement will allow changes in stellar positions to be observed during the mission. This proper motion caused by the stars spatial velocity with respect to the Sun has been measured in the past for a relatively small number of stars by comparing positions measured at widely separated times. The high precision of Hipparcos will, however, be offset by the shortness of the two and a half year observation period so the accuracy of proper motion measurements will not be much increased — the really dramatic improvement will be in the large numbers of stars observed.

The performance of the Hipparcos instrument is closely coupled to the operation of the satellite and the design of both is being refined. The two main difficulties, which should be overcome by the concept first proposed by Lacroute, are the achievement of the necessary precision and the maintenance of the absolute calibration of the angular measurements. A modestly sized telescope will view a beam combiner so that two stars separated on the sky by about 70 degrees will be superimposed in the focal plane on a modulating grid that measures their relative separation. As the satellite rotates the two fields of view will scan along a great circle. By demanding that a closed chain of star separation measurements must sum to 360 degrees angular calibration can be accomplished with the desired frequency. When many intersecting great circle scans are combined the two coordinate stellar position can be found with an ultimate accuracy of one or two milliarc seconds.

There is already a great deal of scientific activity, including colloquia[1,2] and published papers[3-5], supporting the Hipparcos project. ESA has selected two separate consortia to perform the data analysis task and has issued a call for proposals to help define the list of stars to be observed. The deadline of 1 October 1982 gives some hint of how much work is required to put the observing list into the necessary form for the operation of the satellite.

Astrometry from space will still be hard work but at least the astrometric measurements from Hipparcos will stand more clearly above the noise and so attract the attention they deserve from astronomers in general. □

Monoclonal antibodies to human malignant melanoma

from Ralph A. Reisfeld

A RECENT international workshop on monoclonal antibodies to human melanoma-associated antigens* demonstrated rapid progress in the analysis of 30 monoclonal antibodies that had been produced and exchanged by 10 laboratories. There was general agreement that 24 antibodies defined 11 antigens that are expressed on melanoma cells to a considerably greater extent than on other normal or neoplastic cells and tissues. These antigens may be the products of amplified and/or altered normal genes and could provide a set of model targets for adjunct immunotherapy, as well as sensitive molecular probes for studies on the biology of malignant melanoma and the mechanism of neoplastic transformation.

Particularly striking were the consistency among reaction patterns of most antibodies, even though different target cells and techniques were used, and the variety of the antigens identified, even by using the same melanoma cell lines as immunogens. Although most monoclonal antibodies were elicited from melanoma lines in long-term tissue culture, they reacted in binding indirect immunofluorescence and immunoperoxidase assays with surgically removed, frozen tissue sections and, in some cases, with melanoma cell lines at early passage levels — suggesting few tissue culture artefacts and little antigenic drift. Only relatively few antibodies reacted with formalin-fixed, paraffin-embedded tissue sections, suggesting that most determinants recognized by the monoclonal antibodies are irreversibly denatured by this treatment.

Structural studies of the 11 selected antigens indicated 5 of them to be single-chain glycoproteins with molecular weights (M_r) of 70,000–100,000, one a single-chain glycoprotein with M_r 184,000 and two multiple-chain glycoprotein molecules with M_r of 116,000–130,000. One of the antigens is a sialoganglioside (G_{D3}) and two were identified as extracellular matrix proteins, that is, chondroitin sulphate proteoglycans consisting of a glycoprotein chain (M_r 250–280,000) and a series of components with $M_r > 780,000$. Antibodies to two of the antigens, p97 (gp95), a glycoprotein of M_r 97,000 which is structurally related to transferrin, and the proteoglycan molecules, have been identified which can react with distinct epitopes on the same or very similar molecules. Interestingly, all the 24 monoclonal antibodies selected react with cell membrane or matrix antigens. This may reflect a relatively low immunogenicity of cytoplasmic antigens and/or the choice of the procedures used in screening the hybridomas.

Several general conclusions were reached by the 10 participating laboratories. The antibodies analysed detect tumour-associated antigens but not tumour-specific antigens in the strict sense

---

*The workshop on 'Monoclonal Antibodies to Human Melanoma Antigens: II' held on 26–27 April 1982 at Bethesda, Maryland was organized by the Immunology Program, Cancer Biology Branch, Division of Cancer Biology and Diagnosis, National Cancer Institute. The participating laboratories were those of J.C. Bystryn, New York University School of Medicine; S. Ferrone, Columbia University, New York; K.E. and I. Hellstrom, Fred Hutchinson Cancer Center, Seattle; H. Koprowski, Wistar Institute, Philadelphia; J.P. Mach and S. Carrel, Ludwig Institute for Cancer Research, Lausanne; D.L. Morton, University of California, Los Angeles; R.A Reisfeld, Scripps Clinic and Research Foundation, La Jolla; G. Riethmuller, University of Munich; and H.F. Seigler, Duke University Medical Center, Durham. The proceedings of the workshop will be published in *Hybridoma* 2, No. 4, 1982.

Ralph A. Reisfeld is at Scripps Clinic and Research Foundation, La Jolla, California 92037.

0028-0836/82/290325-02$01.00

of the word; those selected are, however, sufficiently closely associated with melanomas that they should be further characterized and serious consideration given to their potential as *in vitro* and *in vivo* markers for diagnosis and as targets for immunotherapy. Simple screening of monoclonal antibodies by binding assays with cultured tumour cell lines is not sufficient to evaluate critically their specificity, and screening of a large variety of both normal and tumour tissues by indirect immunofluorescence or immunoperoxidase techniques appears necessary to make any meaningful comparisons. Quantification of antigen expression on normal and tumour cells is definitely necessary, either by saturation binding with Scatchard plot analyses or by quantitative binding assays with radiolabelled antibody or by analysis with the fluorescence-activated cell sorter. □

What limits photosynthesis?

from Christine Foyer, Richard Leegood and David Walker

ENHANCED plant productivity is one means by which world food and energy shortages may be alleviated. For this reason research into the photosynthetic process is increasingly favoured both in the UK and overseas. However, the crop physiologist is quick to remind us that the connection between photosynthesis and productivity is more apparent than real, in the sense that a correlation between short-term measurement of photosynthetic rate and crop yield is not easily demonstrated. Certainly the gulf between the plant scientist and the farmer is considerable. Even the highly valuable contributions of the plant breeder have been largely confined to factors such as disease resistance and the redistribution of assimilates within the plant. We have all lamented photorespiratory loss, worried over the inadequacies of ribulose bisphosphate carboxylase/oxygenase and wondered if we can turn, for solace, to C4. Perhaps, however, if we pause for thought, there is no reason to be unduly pessimistic about the future of photosynthesis in its relation to agriculture.

Plant growth is the best measure of net photosynthesis that we have and the limits to which the useful redistribution of assimilates can be achieved are fast being reached. To increase plant productivity by securing more vigorous growth through more effective photosynthesis we need to determine which existing limitation might be removed. A discussion meeting* was organized by the Agricultural Research Council to identify and characterize the reactions which limit the photosynthetic process in various environmental and developmental conditions, and to determine how basic research into photosynthesis may be directed towards increasing plant productivity. A workshop on the methodology and applications of the measurement of chlorophyll fluorescence preceded the meeting. This technique is now regarded as a valuable non-intrusive probe for photosynthesis *in vivo* providing, in the words of J. Barber (Imperial College, London), a 'stethoscope' for plants.

Many workers in photosynthesis disagree about the basis on which the rate of photosynthesis should be expressed, and doubt the validity of the present methods, especially since a single factor is unlikely to be constant. All quantitative means for expressing photosynthetic rate in current use (for example, ground area, fresh weight) carry inescapable disadvantages. In spite of this, chlorophyll is likely to remain the universal basis for expressing photosynthetic rate at the cellular level simply because it is easily measured (J. Ludwig, GCRI, Littlehampton). The use of the term 'photosynthetic efficacy', to relate capacity to performance (that is, an assessment of the actual performance of a given crop as a function of the potential performance), could help to determine the degree to which photosynthetic capacity is realized in a given circumstance (D. A. Walker, Sheffield University).

Although the basic climatic limitation to crop photosynthesis is the seasonal input of light energy, the degree to which this energy can be used by the plant is modified by local climatic factors, such as temperature, water and the requirements of particular farming systems (J. P. Cooper, WPBI, Aberystwyth). The rate of photosynthesis reaches a maximum at or just before full leaf expansion and declines thereafter. The length of the growing season before leaf senescence is, therefore, a limitation on crop yield (H. Thomas, WPBI, Aberystwyth). The efficiency of photosynthesis in relation to the balanced excitation of the photosystems is believed to be controlled by the phosphorylation of the light-harvesting chlorophyll *a/b* binding protein. Balanced excitation is necessary for efficient non-cyclic electron transport and also serves to poise cyclic electron flow by increasing excitation of photosystem I relative to photosystem II. Furthermore, the flexible distribution of available quanta between the two photosystems can be especially important under stress and allow a more efficient distribution of excitation in different cells of a leaf and different leaves in a canopy (P. Horton, Sheffield University).

The majority of temperature crops, particularly cereals, are exposed to suboptimal temperatures for most of their lives. Dramatic differences in temperature response occur between cold-tolerant and cold-intolerant plants. Even at the level of the chloroplast the partitioning of assimilate may be considerably influenced by temperature as transport generally outstrips production at low temperatures; the autocatalytic Benson–Calvin Cycle does not obey Arrhenius' law (Heber, Würzburg University). Low temperatures cause phase changes in the lipids of the thylakoid membranes and the resulting reduction of the fluidity of the thylakoids reduces the mobility of the electron carriers between photosystems I and II, for example by diminishing the diffusion rate of reduced plastoquinone (D. Chapman, Imperial College, London). This may well be the most temperature-dependent step of electron transport.

Ribulose bisphosphate carboxylase/oxygenase is the point of entry of carbon into the Benson–Calvin cycle and that of oxygen into the photorespiratory pathway. There is a broad correlation between ribulose bisphosphate carboxylase activity extractable from leaves and light-saturated rates of photosynthesis in plants taken from a wide range of growth conditions and genotypes. Ribulose bisphosphate carboxylase appears to limit photosynthesis only in the sense that the activity of the enzyme is close to that of the flux through the Benson–Calvin cycle. Plants synthesize only as much of this enzyme as they need (A. Keys, Rothamsted Experimental Station). This raises the question of whether a limitation imposed by this enzyme is a phenomenon perceived by the manipulator rather than the plant.

The purpose of photorespiration continues to be hotly debated. Selective inhibition of the oxygenase activity is improbable although some species have carboxylases with a significantly higher affinity for CO_2 than others (S. Gutteridge, Rothamsted Experimental Station). Other enzymes of the Benson–Calvin cycle, such as fructose bisphosphatase, show changes in activity in response to the redox state of ferredoxin, although the changes in fructose bisphosphatase activity do not have a role in regulation of the photosynthetic rate in leaves illuminated with saturating light.

No final answer as to 'What limits photosynthesis' arose from the meeting. The most popular candidate, proposed by O. Björkman (Carnegie Institute of Washington), was God. The question deserves future consideration and research if we are to secure increased plant productivity. □

Christine Foyer, Richard Leegood and David Walker are in the ARC Research Group on Photosynthesis, Department of Botany, Sheffied S10 2TN.

---

*The ARC discussion meeting on 'What limits photosynthesis' was held on 15–16 April 1982 and was hosted by the ARC Research Group on Photosynthesis at the University of Sheffield.

New views of the immunoglobulin heavy-chain switch

from Kenneth B. Marcu and Max D. Cooper

DURING the differentiation of B lymphocytes, the immunoglobulin genes they express undergo a succession of rearrangements. The last of these determines the class of antibody expressed — whether it is IgM, IgG, IgA and so on. Just which of these classes or isotypes will predominate in an antibody response depends, among other things, on the nature of the antigen and in particular on the dependence of the B-cell response on T-cell help. Both the mechanism of the class switch and the nature of the T-cell influence were discussed at a meeting* in Sweden.

Antibody molecules (or immunoglobulins) consist of two identical heavy and light chains. In the mouse, these are encoded by linked families of V_H, D_H and J_H genes located 5′ to a cluster of eight heavy-chain constant-region (C_H) genes (μ, δ, $\gamma 3$, $\gamma 1$, $\gamma 2b$, $\gamma 2a$, ε and α) on chromosome 12 and V_L and J_L genes upstream from the κ and λ light-chain genes on chromosomes 6 and 16 respectively.

One of the first steps in differentiation of the B cell is the assembly by chromosomal rearrangement of one each of the V_H, D_H and J_H genes and the transcription of the V–D–J set along with the C_μ gene (see the figure). A cell expressing such μ mRNA is known as a pre-B cell, and at this stage few of the μ chains reach the cell surface. Thus the pre-B cell is not influenced by antigen until the next stage in differentiation, when one set of V_L and J_L genes is productively rearranged and a complete IgM molecule is expressed on the surface of the cell, which has now differentiated into an immature B lymphocyte.

Subsequent stages in B-cell differentiation entail changes in the expression of the C_H genes, and, in particular, isotype switching in which the same V_H–D_H–J_H set is expressed sequentially with different constant-region genes. Intermediate stages in B-lymphocyte differentiation are marked by the expression of a variety of cell-surface proteins involved in regulating B-cell migration, growth and differentiation. In its terminally differentiated state, the B cell, now a plasma cell, shifts from surface expression to secretion of its antibody.

All immature B lymphocytes at first express membrane-bound IgM, and later co-express surface IgD, sharing the same V_H–D_H–J_H and light chains. Some members of each B-cell clone make a further switch, from IgM (and IgD) to IgG, IgA or IgE — again with no change in the V–D–J genes. Heavy-chain isotype switching in B-cell clones was discovered more than a decade ago, when it was shown that treatment of immature B cells by infusions of anti-μ antibodies prevented subsequent development of plasma cells producing other immunoglobulin classes[1]. It is now known that in plasmacytomas secreting isotypes other than μ, the constant-region genes 5′ to the one that is expressed are deleted, the deletion occurring between switch (S) regions localized in the introns 5′ to the expressed C_γ, C_ε or C_α gene[2–6]. But many fundamental questions remain unanswered. What is the normal sequence of C_H gene expression — can cells switch directly from IgM to, say, IgE or must they express each successive isotype between? What are the precise switch mechanisms and when does a cell become committed? How is the switch regulated? The answers to these questions are beginning to emerge and were discussed at Umeå.

Mechanism of the switch

While it is generally accepted that deletion of the 5′ constant-region genes accompanies differentiation into an immunoglobulin-secreting plasma cell, it is still not known whether this occurs by intrachromosomal deletion[2] or by unequal exchange between sister chromatids[7]. In either case, there is now evidence that the C_H gene deletion may not occur until the switch from the surface to secreted immunoglobulin has taken place.

The existence of immature B lymphocytes exhibiting two cell-surface isotypes, for example IgM + IgG or IgM + IgA, has been known for some time. It was originally thought that this could be most simply explained by the stability of either the μ mRNA or the μ polypeptide, which would allow for the maintenance of cell-surface IgM for a B cell that has already genetically switched to either γ or α isotype. In the case of cells co-expressing μ and δ chains, however, it is now known that the two chains are produced by differential splicing of a single primary RNA transcript containing both the C_μ and the C_δ gene[8–10]. At the meeting it became clear that differential splicing of a long transcript may also underlie the expression of constant-region genes downstream of δ. T. Honjo (Osaka University) presented evidence that $\mu^+ \varepsilon^+$ B lymphocytes, purified from the spleens of parasite-infected SJA/9 mice (a congenic strain without detectable circulating IgE antibody), have no detectable C_H gene rearrangements and/or deletions. To explain this unexpected finding, Honjo proposes[23] that a transcription unit starting 5′ of V_H

In the course of B cell ontogeny, V_H, D_H and J_H DNA segments first become assembled to encode a complete heavy-chain variable region and later, the same assembly of V, D and J segments is associated sequentially with different C segments. The diagram shows the three possible ways in which this sequential switching may be achieved.

---

*A workshop on 'Immunoglobulin Heavy-Chain Class Switching' was organized by A. Coutinho and his colleagues at Umeå University, Sweden, on 16–19 February 1982.

Kenneth B. Marcu is at the Department of Biochemistry, State University of New York at Stony Brook, New York 11794, and Max D. Cooper is at the Cellular Immunobiology Unit, University of Alabama Medical Center, Birmingham, Alabama 35294.

0028-0836/82/290327-02$01.00

and terminating past ε is produced in $\mu^+ \varepsilon^+$ lymphocytes. This approximately 180 kilobase multi-C_H transcript could yield μ and ε membrane mRNAs by differential RNA splicing coupled with specific poly(A) addition (see the figure). Similar studies on a population of $\mu^+ \gamma 1^+$ B cells from normal mouse spleen have been interpreted in the same way[11]. However, cellular immunologists will want clear assurance that the immunoglobulin molecules on the surface of these cells are actually synthesized by them and not picked up from other cells, especially since the existence of a multi-C_H transcript in immature B lymphocytes may be very difficult to establish (none has yet been isolated for the μ–δ transcription unit). This hypothesis poses the intriguing problem of a mechanism for operating the switch first by RNA splicing and then by DNA rearrangement since γ^+ and α^+ B cells have been shown to give rise to plasma cells which produce the same heavy chain isotype.

Another hypothesis arises from observations on subclones of a pre-B cell line (18–81) transformed by Abelson virus. In these cells, switching from μ to γ2b (ref. 12) can apparently occur in the absence of μ-gene deletion, though not without some DNA rearrangement[13]. It is possible that at some point in the history of the 18–81 cell line, the δ, γ3 and γ1 genes were deleted and the γ2b gene was positioned immediately 3′ to the μ gene where it could give rise to a μ–γ2b transcript by the same mechanism that produces the μ–δ transcript. F. Blattner (University of Wisconsin) suggested that this might be a transitional step in isotype switching, the constant-region gene to be expressed in each case replacing the δ gene 3′ to μ. The next step would involve C_μ gene deletion before plasma cell differentiation.

Successive and direct switching

So far, there is evidence for both successive and direct isotype switching (see the figure). Both switching modes could operate on a purely stochastic basis[5], or under the influence of regulatory elements such as isotype-specific recombinases[14].

In addition to direct $\mu \rightarrow \gamma$ and $\mu \rightarrow \alpha$ switches, M. Wabl (University of Tübingen) reported evidence for a $\mu \rightarrow \varepsilon$ switch in lipopolysaccharide (LPS)-induced plasma blasts. Successive isotype switches are also suggested from studies using the splenic focus assay and limiting dilution as methods for examining these cell clones[15,16]. Using the limiting dilution of LPS-stimulated cells, A. Coutinho and co-workers (Umeå University) obtained results consistent with switches from μ to each of the other isotypes and for multiple patterns of successive 'downstream' switches. In the response to trinitrophenol-Ficoll, a T-independent antigen, the frequency of γ isotypes expressed follows the C_H gene order (that is, $\gamma3 > \gamma1 > \gamma2b > \gamma2a$), and results of splenic focus analysis suggested that γ3 cells may be pivotal for switches to other γ isotypes[16]. K. Marcu (SUNY, Stony Brook) showed that $S_{\gamma 3}$, S_α and S_ε possess extensive homology with S_μ, while $S_{\gamma 1}$, $S_{\gamma 2b}$ and $S_{\gamma 2a}$ have very limited S_μ homology, and suggested that this could provide a genetic basis for intermediate $S_{\gamma 3}$ switches to other γ isotypes (see the figure). Marcu also presented evidence for a new consensus DNA sequence, YAGGTTG, preferentially located 5′ of C_H switch sites and repeated in S regions[17,18], which, together with previously identified common S sequences (GAGCT and GGGGT)[19], may play a part in switch-site recognition[17–19].

Successive C_H gene switches have recently been explored at the molecular level in C_H switch-variant cell lines[20,21]. A switch from γ2b to γ2a in MPC-11 myeloma variants results in S region-mediated γ2b gene deletion[20]. F. Sablitzky (Genetics Institute, University of Cologne) presented some startling results from correlations of C_H gene rearrangements and deletions with isotype switching in clones of spontaneous class-switch variants derived from the X-63 hybridoma[15]. In X-63 hybridoma cells, 'backswitches' (for example $\gamma 2a \rightarrow \gamma 1$) occur at 100-fold higher frequency than forward switches (for example $\gamma 1 \rightarrow \gamma 2b \rightarrow \gamma 2a$), which arise at frequencies of 10^{-7}. The unprecedented finding of C_H backswitching could be most simply explained by either trans-homologous chromosome exchange or the presence of duplicated γ genes generated by unequal cross-over during sister chromatid exchange. Even though these findings may partly reflect peculiarities of the cell lines, they do clearly demonstrate that successive switching — for example, $\gamma 1 \rightarrow \gamma 2b \rightarrow \gamma 2a$ — can occur.

Role of T cells in isotype expression

It is well known that the nature of the antigen and responding T cells or their helper and suppressor factors can selectively influence the isotypes expressed by plasma cell progeny of responding B cells. J. Davies (Washington University, St Louis) reviewed evidence indicating that T-independent polysaccharide antigens elicit primarily μ and γ3 antibodies while the T-dependent protein antigens preferentially induce μ, γ1 and γ2 antibodies in the mouse. Coutinho showed that the same hapten can elicit different antibody isotypes when coupled to different carriers which determine the nature of the T-cell help. Y. Rosenberg (MRC, Mill Hill) showed that the isotype-specific influence of antigen-stimulated T cells may spill over to cause bystander B-cell clones to undergo plasma cell differentiation, the T-cell influence presumably being mediated by soluble factors.

Three groups of investigators represented at the Umeå meeting have analysed the immunoglobulin isotypes expressed by mouse B cells when cultured with established T-cell lines (A. Coutinho; and L. Forni, Basel) or soluble T-cell factors (P. Tucker, Dallas; & E. Severinsson, University of Stockholm). In each system, the polyclonal B-cell activator LPS by itself induced γ3 more than γ1 plasma cells. The addition of activated T cells, or soluble factors released from them favoured the reverse pattern, γ1 over γ3. L. Forni's data suggested that LPS induces both γ1 and γ3 B-cell blasts to proliferate, but only the γ3 blasts to differentiate into mature plasma cells; the subsequent addition of activated T cells, by contrast, reduces the frequency of γ3 cells and induces γ1 plasma cells. P. Tucker presented data on the state of the γ3 and γ1 mRNA species before and after the addition of a T-cell product (B-cell differentiation factor[22]) to LPS-stimulated B cells. LPS alone induced γ3 mRNAs, but very little γ1 mRNA. Following the addition of the T-cell factor, γ1 mRNAs were increased in quantity and γ3 mRNAs reduced. But all these results, while tantalizing, leave open the central question: do T cells instruct B cells to switch isotypes or do they select isotype-committed B cells for preferential induction of terminal differentiation?

Clearly, we still have important lessons to learn about the genetic basis for C_H isotype switching and its regulation. While solutions appear almost within reach, these genetic events remain elusive as they occur transiently and in minor subpopulations of cells. Clones of normal B cells undergoing isotype switches are unavailable. The C_H switching phenomenon may continue to challenge both cellular and molecular biologists for some time ☐

The sequence of α_1–antitrypsin is in keeping with its role as a tissue scavenger of leukocyte elastase. Two abnormal variants commonly present in Europeans cause a deficiency that predisposes them to a progressive loss of lung elasticity. The nature of the reactive centre helps explain why cigarette smoking greatly accelerates the onset and severity of this degenerative process to give the disease emphysema.

As its name implies, α_1-antitrypsin (α_1–AT) is the major component of the α_1 electrophoretic band of the human plasma proteins and acts as an inhibitor of proteolytic enzymes. It inhibits serine proteinases and hence is also known as α_1-proteinase inhibitor. Interest in this protein stems largely from the observation that its genetic deficiency[1] is accompanied by the early onset of degenerative lung disease[2] and, in some instances, liver disease[3]. A puzzling feature of this genetic deficiency is its virtual confinement to Europeans, some 10% of whom are carriers of a pathological variant[4,5].

This association with disease has stimulated research into the structure and abnormalities of α_1–AT that is revealing new aspects of the molecular pathology of genetic disease. One example[6,7] is the way that genetic and environmental factors may interact to give disease. α_1–AT is a protective factor and its genetic deficiency renders the individual susceptible to cumulative lung damage from bouts of inflammation induced by outside stress such as pollutants. The proteolytic enzymes released during this inflammation can overwhelm the limited amounts of inhibitor present in the deficient individual, a situation that is aggravated by the additional ability of some pollutants to produce a direct inactivation of α_1–AT. The consequence is that whereas in a healthy environment α_1–AT deficiency may be compatible with a full lifespan, in a polluted environment or with heavy cigarette smoking it can result in crippling lung disease and early death[8].

This review discusses α_1–AT, its variants and their molecular pathology, with particular reference to the primary structure of the protein presented here in its completed form.

Structure

The structure of human α_1–AT shown in Fig. 1 is based on our amino acid sequence of the plasma protein and represents a consensus with that of the unpublished cDNA sequence of human α_1–AT (S. L. C. Woo and E. W. Davie, personal communication). Details of the sequence and its determination are given in Fig. 1 legend.

The structural features of α_1–AT are in keeping with its known functions. The molecule is relatively small and polar, allowing ready movement into the tissue fluids. It has a single polypeptide chain of 394 residues, with three carbohydrate side chains[9,10], giving an overall molecular weight of 51,000. The cDNA studies[11] confirm that α_1–AT does not have a propeptide but does have a 24-residue hydrophobic pre- or signal peptide[12]. The molecule has a single reactive site[13], centred on methionine[14] at position 358. For α_1–AT to act as a proteinase inhibitor, this reactive site must be held in a fixed conformation: the conformation of an ideal substrate[15]. Although the tertiary structure of α_1–AT is not known, physical measurements[16,17] and calculations[18] predict a highly ordered structure. The strength of this ordered structure is indicated by the fact that it is not buttressed by the disulphide bridges that are characteristic of most inhibitors, including the homologous antithrombin-III[19]. α_1–AT has only the one cysteine residue, located in a cavity on the surface of the molecule and available for SH–SS interchange reactions both *in vivo* and *in vitro*.[20]

A characteristic feature of α_1–AT is the multiple banding that it shows on acid electrophoresis (pH 4.9)[21] or on electrofocusing[22]. This banding is the result of a microheterogeneity that is primarily due to variations in its carbohydrate structure[23]. The three oligosaccharide groups of α_1–AT are N-linked to asparagine residues at positions 46, 83 and 247.[10] A physiologically controlled variation can occur in the structure of these side chains to give isoforms; physiological variants of α_1–AT in which the usual biantennary oligosaccharides may be replaced in position 83, and to a lesser extent 46, by triantennary oligosaccharides [9,23] (Fig. 2).

Reactive centre: Although it has been generally agreed that the reactive site of α_1–AT is centred on a methionine residue[14], its location in the sequence and the number of reactive sites has been controversial[13,14,24-26]. The overall sequence shows that the reactive centre methionine is Met 358, 37 residues from the C-terminus of the molecule[13,27,28].

Proteinase inhibition is accompanied by the formation of a 1:1 complex between α_1–AT and its target enzyme.[29] The reaction mimics that between the enzyme and its substrate, with the reactive centre of the inhibitor functioning as a bait for the active site of the proteinase. The mechanism of inhibition appears to involve a blockage of the reaction, probably at the stage of the tetrahedral adduct, and the evidence suggests that cleavage does not occur in physiological conditions[26]. Conversion of the adduct to an acyl-enzyme may be induced by gross changes in pH or by treatment with strong denaturing agents; only in these non-physiological conditions can the existence of the C-terminal, 36 residue, leaving group be demonstrated[28].

Homology: An interesting feature of the sequence of α_1–AT is its homology with those of antithrombin-III[19,30] and ovalbumin[31] (Fig. 1). It shares 29% common structure with antithrombin-III and 30% with ovalbumin, and ovalbumin and antithrombin-III share 32% common structure with each other. Together the three form a new superfamily[31] that probably diverged from a common ancestral proteinase inhibitor some 500 million years ago. However, this suggestion of a common origin has been questioned as a consequence of gene sequence studies[32] that indicate a complete difference in intron positions between α_1–AT, with three introns, and ovalbumin, with seven introns. This has raised the possibility that the similarity of the two proteins may be due to convergent evolution. However, comparison of aromatic amino acids (Fig. 1) confirms that the structural similarity of α_1–AT and ovalbumin extends

Fig. 1 The sequence of human α_1–AT aligned with that of human antithrombin-III[19] and chicken ovalbumin[68]. Sequence numbers refer to α_1–AT. The reactive centre Met-Ser 358–359 is boxed; the attachment points of the three oligosaccharide chains at Asn 46, Asn 83 and Asn 247 are encircled; ▼ shows the mutation sites of the *S* (264 Glu → Val) and *Z* (342 Glu → Lys) variants. Residues aligned with the bulky aromatic Phe and Trp of ovalbumin are shaded to indicate that structural homology is not confined to a single domain of the molecule; this confirms a relationship derived from divergent evolution. Homology of the reactive centre region 358–363 of α_1–AT and antithrombin-III is illustrated in Fig. 3; ovalbumin retains some homology at this site, although it apparently has no inhibitory function. There has also been some conservation in α^1–AT of the internal site (244–261) identified in ovalbumin as a hydrophobic signal sequence[71], but α_1–AT has an undoubted N-terminal signal sequence[11,12]. There are several striking differences as well as the difference in intron numbers and positions. There are three disulphide bonds in antithrombin-III, one in ovalbumin and none in α_1–AT; ovalbumin has a single oligosaccharide group, antithrombin-III has four and α_1–AT has three, none of the sites being homologously related. α_1–AT has a calculated molecular weight of 51,000 with a 13% carbohydrate content (isoform I). The sequence of human α_1–AT is based on our previously published peptide sequences[10,27,30] along with recent completion of overlap sequences. The sequence has been checked against that of the unpublished cDNA sequence for human α_1–AT (S. L. C. Woo and E. W. Davie, personal communication). Residue Leu 176, and amide assignments 158 and 159, have been made on the basis of the cDNA structure. The only sequence difference is at 213 where we obtain an unequivocal Val but the cDNA shows an Ala; this may represent a polymorphism. Our sequence gives a consistent Asp–Gly at 116–117 but post-synthetic deamidation is known to occur at Asn–Gly sequences[69,70] and residue 116 has therefore been assigned as an Asn, as found in the cDNA.

throughout the sequence. This would be highly improbable if the similarity were due to convergence.

The relationship of the two plasma proteins, α_1–AT and antithrombin-III, is not surprising. Both are serine proteinase inhibitors and both have become specialized to varying degrees as inhibitors of specific enzymes. This is most marked with antithrombin-III, which is a specific inhibitor of the coagulation proteinases. By comparison, α_1–AT is relatively unspecialized and will inhibit all serine proteinases including thrombin, its most effective target being leukocyte elastase[33,34]. An examination of the differences between the two inhibitors provides a clue as to the process involved in their specialization. Calculation of the evolutionary distance between α_1–AT and antithrombin-III gives a value of 160 accepted point mutations per 100 residues, which is similar to that between thrombin and elastase[13]. This similarity suggests that the specialization of the inhibitors has occurred in response to, and in concert with, the specialization of their target enzymes.

The alignment of the two sequences provides strong evidence for the positioning of their reactive centres, giving support[27] for a reactive centre in antithrombin-III at Arg 384. The similarity between these two proteins is an example of divergent evolution but, interestingly, the recognition of the sequence of the reactive centre of α_1–AT was greatly aided by a set of convergent homologies[14]. Figure 3 shows the remarkable similarity between the reactive centres of both proteins and those of the unrelated plant proteinase inhibitors.

Other features of the homology of the proteins are indicated in Fig. 1. One point of interest is that the 32-residue N-terminal portion of α_1–AT, which bears no resemblance to the other two proteins[10], is homologous to another plasma proteinase inhibitor, α_1-antichymotrypsin[35]. This has a similar function to that of α_1–AT as an inhibitor of a leukocyte enzyme, probably cathepsin G[33].

Function

There is good reason to believe that α_1–AT is primarily a defence protein whose function is to protect the tissues against attack from released proteolytic enzymes. It is synthesized in the liver and secreted into the plasma where it has a half life of 6 days[36]. As would be expected of a defence protein, it is an acute phase reactant and its normal plasma concentration[37] of 1.3 g l^{-1} can quadruple in response to the general stimulus of inflammation or oestrogens. This rise in plasma concentration is due to an increased synthesis of α_1–AT, particularly of its triantennary isoforms[38] (Fig. 2). The only other inhibitor present in blood in concentrations approaching that of α_1-AT is the much larger α_2-macroglobulin. Both inhibitors function as suicidal proteins that are taken up by the cells of the reticuloendothelial system once they have formed complexes with their target proteinases[39].

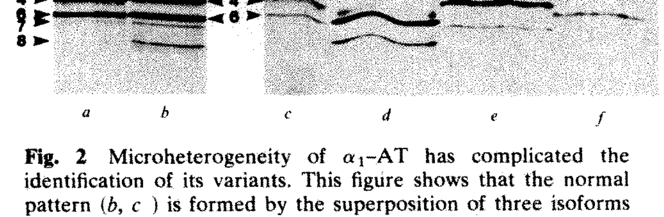

Fig. 2 Microheterogeneity of α_1–AT has complicated the identification of its variants. This figure shows that the normal pattern (*b*, *c*) is formed by the superposition of three isoforms (*d*, *e*, *f*). The isoforms differ in the degree of branching of their oligosaccharide groups and consequently in the number of their negatively charged sialic acids. Isoform I (*d*) has all biantennary chains and isoforms II (*e*) and III (*f*) have one and two, respectively, of these replaced by triantennary chains. The pattern is complicated by a subsidiary heterogeneity seen in each isoform that is explicable by known minor post-secretory changes in primary structure. A shift to increased production of isoforms II and III during inflammation results in an increased proportion of bands 2 and 4 (*a*). (Reproduced with permission from ref. 38.)

Fig. 3 The reactive centres of α_1–AT and antithrombin-III bear a striking similarity to those of the much smaller and unrelated plant proteinase inhibitors[14]. The P_1 residue reflects the specificity of the target enzyme. Elastase preferentially cleaves at small hydrophobic residues such as alanine (as in the garden bean inhibitor) and valine. Methionine is found in some other inhibitors of elastase;[15] it probably confers a wider specificity but also its lability may be of advantage in allowing the deactivation of the inhibitor.

The evidence that the prime target of α_1–AT is leukocyte elastase is circumstantial but persuasive. The strongest evidence is the consequences of deficiency; the major effect is a progressive loss of elasticity in the lung, a loss that can be mimicked in model systems by the administration of elastase aerosols[40]. Secondary evidence is provided by the measurement of the association rate constants of α_1–AT with a range of proteinases[33]. These give a decreasing order with: leukocyte elastase > chymotrypsin > cathepsin G > anionic trypsin > cationic trypsin > plasmin > thrombin. These association rate constants together with clinical and *in vivo* experimental observations indicate that α_1–AT is a physiologically effective inhibitor of leukocyte elastase[39,41] but a relatively ineffective inhibitor of trypsin, plasmin and thrombin.

An initially puzzling aspect of the role of α_1–AT as a specific inhibitor of elastase is the occurrence of methionine at its reactive centre. Methionine in a Pro-Met sequence will provide a susceptible point for cleavage by elastase but valine[42] or alanine would seem to be a better and more specific choice. Furthermore, methionine has the apparent disadvantage of being readily oxidized to its sulphoxide which is polar and does not provide a favourable proteolytic cleavage site for elastase[43,44]. Consequently, α_1–AT is readily inactivated by oxidizing agents such as the oxygen radicals released by phagocytes[45,46]. However, a mechanism can be proposed in which this lability may provide a self-regulatory contribution to the process of inflammation.

Consider the formation of an abscess around a small foreign particle. An aggregation of leukocytes occurs to surround the particle and perform two separate functions—a discharge of bactericidal oxygen radicals and a release of granulocytic enzymes, including[47] elastase and cathepsin G. These enzymes facilitate the breakdown of adjacent connective tissue to give an area of liquefaction which isolates the foreign body in readiness for ejection. The spread of this liquefactive process by diffusion of the enzymes will be constrained by tissue proteinase inhibitors, predominantly α_1–AT. This will limit tissue breakdown at the periphery of the inflammation, but allow it to occur at the focus of activity where α_1–AT will itself be inhibited by released oxygen free radicals. In this way the lability of the methionine at the reactive centre of α_1–AT could be advantageous, if it allowed the inhibition to be switched off at the focus of inflammation but continued to provide protection for outlying tissue.

However, the lability of α_1–AT to oxidation will be distinctly disadvantageous in exposed situations such as occur in the fluids lining the respiratory tract. The elastic tissue of the lung is protected from surface attack primarily by two inhibitors: human bronchial inhibitor which predominates in the fluid lining the upper respiratory tract[34,41] and α_1–AT which predominates in the lower respiratory tract[7,34,41]. Normally there is ample inhibitory capacity but the defences of the lower respiratory tract, because they depend on α_1–AT, are vulnerable to combined oxidative and elastolytic attack, as is believed to occur as a consequence of heavy cigarette smoking[48].

Variation and disease

Genetic variation: There are several well established genetic polymorphisms of α_1-AT. The protein is encoded by two independent alleles at a single locus, resulting in autosomal codominant inheritance. The variants are classified alphabetically by the *Pi* (proteinase inhibitor) nomenclature[21], in terms of their electrophoretic mobility at *p*H 4.9. For example, *PiBB* is the homozygote for an anodal variant and *PiZZ* for a cathodal variant, with *PiMM* representing the homozygote for the normal *M* allele.

The variants of particular interest are the common *Z* and *S* mutants which are associated with plasma deficiency; the product of the *Z* allele gives concentrations equivalent to 15% of that of the normal *M* allele, whereas the product of the *S* allele gives concentrations of 60% of the normal allele[49]. Mixed heterozygotes, for example *MZ*, *MS* and *SZ*, will give proportionately altered plasma levels. The genotypes with a deficiency sufficient to pose a definite risk to health are: *PiZZ* (15% of normal concentration), *PiSZ* (35% of normal) and combinations with the unusual null (−) gene, for example, *PiZ*− (8% of normal).

The structural abnormalities of the *Z* and *S* variants have been characterized[50–52]. Both have single amino acid substitutions (Fig. 1) that have presumably arisen from single base mutations in the gene DNA. Otherwise the plasma forms of the two variants resemble the normal M protein; they have a similar half life in the circulation[37], normal inhibitory capacity and a similar carbohydrate composition. The Z protein, however, is something of an exception in that it is only partially secreted, and a considerable amount of the protein accumulates at the site of synthesis in the endoplasmic reticulum of the liver cells[3].

A summary of the findings of various populations surveys[5] shows that the *S* and *Z* variants are polymorphisms essentially confined to individuals of European descent. On average, some 3% of Europeans are carriers of the *Z* mutant (*PiMZ*) and some 7% are carriers of the *S* gene (*PiMS*). The frequency of the Z gene is somewhat higher in Northern Europeans and conversely that of the *S* gene is somewhat higher in Southern Europeans. About 1 in 1,000 Northern Europeans will have the *PiZZ* or *PiSZ* genotypes associated with severe deficiency of α_1-AT[53]. The relative confinement of these polymorphisms to the European is a puzzle. Both of the deficiency genes pose a real threat to health and there must be some balancing advantage to explain their survival at this frequency.

Deficiency and disease: Abnormal phenotypes of α_1-AT have been associated with a number of diseases[54] including renal disease, arthritis and malignancies. However, the two strongest associations are with lung and liver disease; 60% of those with severe deficiency will die of lung disease and 14% of those with the *ZZ* deficiency will die of liver disease[8]. Two separate features need to be considered regarding the pathology of these diseases in α_1-AT deficiency. These are the liver accumulation of the variant and the low plasma concentrations of inhibitor.

The accumulation of α_1-AT in the hepatocytes occurs only with those variants whose defect is assumed to be one of secretion, the *Z* variant being by far the most common example[55]. The *Z* protein that accumulates in the liver apparently has the same polypeptide structure[56] as the circulating Z protein, but its carbohydrate side chains are immature, with a high mannose content and no sialic acid[56,57]. This is compatible with the deficiency of the Z protein being due to a partial block in processing of the polypeptide, with some of the material proceeding to completion and subsequent secretion in the plasma whilst the remainder is stopped in its passage through the secretory pathway at the stage of partial glycosylation[5]. The accumulation takes the form of intracellular amorphous aggregations of α_1-AT that can be demonstrated microscopically as occasional deposits in the *PiMZ* liver and as massive deposits in the *PiZZ* liver (Fig. 4).

Liver disease is most apparent in the *PiZZ* newborn, where it occurs as a hepatitis with a wide variation in severity[58]. Some 50% of *PiZZ* infants have minor changes in liver function, some 7% develop a severe obstructive jaundice, and a smaller proportion go on to develop a fatal juvenile cirrhosis. The reason for this variation in severity is not known; there are probably a number of contributory factors, such as hormonal influences, since boys are more affected than girls, and genetic influences, since a familial predisposition seems to be involved[58]. Although the childhood cirrhosis is the most obvious and tragic form of the liver disease there is also an independent and substantial risk of developing cirrhosis in adult life. This increases with age to give cirrhosis levels near 20% in *PiZZ* individuals above the age[8] of 50. The pathophysiology of this liver disease is not understood. It is almost certainly related to the accumulation of α_1-AT in the hepatocyte rather than the associated plasma deficiency, because it only occurs in association with those variants that produce inclusions[5] and not with those, such as the *S* variant, that give an isolated plasma deficiency.

However, there is no doubt that the lung disease is a direct consequence of low plasma levels of α_1-AT. This conclusion is supported by a large body of evidence, both observational and experimental, that has been reviewed elsewhere[6,7]. It all indicates that the loss of lung elasticity that occurs in severe α_1-AT deficiency represents the summation of cumulative proteolytic damage. The end point of this loss of elasticity is the development of the irreversible lung disease, emphysema. This is a common disease and only some 1–2% of cases are due to a genetic deficiency of α_1-AT; however, the recognition of this relationship has opened up an understanding of the pathogenesis of emphysema in general as being due to a 'protease–antiprotease' imbalance[7,59].

The most common cause of emphysema is heavy cigarette smoking. Exposure of the lungs to tobacco smoke causes a considerable increase in the population of a phagocytic cell peculiar to the lung, the pulmonary alveolar macrophage[6,7]. The numbers of these in the lung increase up to 10-fold or more in proportion to the number of cigarettes smoked. The macrophages change in character and become activated to give increased proteolytic activity along with the secretion of a chemotactic factor that attracts leukocytes to the lungs[7]. This leads to a considerable change in the phagocytic population of the lung with a large increase in the elastolytic load. There is also an accompanying diminution of proteinase inhibitory capacity, due to an inactivation of inhibitor rather than a deficiency[44]. Normal amounts of α_1-AT are present in bronchial washings but its inhibitory capacity is almost halved[48]. Some of this loss may be due to direct oxidation of the reactive methionine of α_1-AT by cigarette smoke[60] but the main source of oxidation is almost certainly macrophage and leukocyte oxygen radicals[46,61]. The conclusion is that a combination of

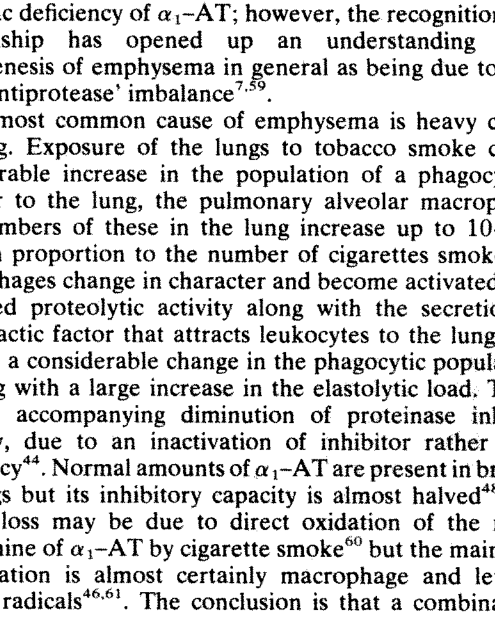

Fig. 4 Electron micrograph (×26,500) of a liver cell showing the accumulation of *Z* variant α_1-AT in the rough endoplasmic reticulum. The position of the inclusions and their composition are compatible with a blockage occurring at the stage of final processing of the oligosaccharide side-chains. These inclusions are clearly visible by light microscopy and can be specifically identified[3] with fluorescent antibody to α_1-AT.

the increased production of elastase along with the decrease in inhibitor activity results in an attack on the elastic tissue of the lower respiratory tract to give the development of emphysema[6,7,48].

The heavy cigarette smoker with homozygous α_1-AT deficiency is in double jeopardy and faces the likelihood of crippling emphysema before the age of 40 years[62] with a 20-year decrease in survival time as compared with the non-smoking homozygote[8]. This situation illustrates the interaction that occurs between environmental and genetic factors. On the one hand there is the risk posed by macrophage stimulation due to smoking and air pollution; on the other, there is a whole range of genetic deficiencies of the proteinase inhibitor. For example, an intermediate deficiency such as *PiSZ* may be compatible with a fully active life for the non-smoking office worker[58], whereas it can result in premature emphysema in a heavily-smoking industrial worker. Fortunately, the common heterozygous genotypes, *PiMS* and *PiMZ*, pose no real threat to respiratory health[63,64].

Molecular pathology: There is now no doubt that the common *Z* and *S* deficiencies of α_1-AT are due to single amino acid substitutions in its polypeptide chain. Independent analyses of plasma samples from several unrelated individuals have shown the change in structure in the *S* variant to be the replacement of glutamic acid by valine at position 264 and in the *Z* variant the replacement of glutamic acid by lysine at position 342[18,50-52,65].

In the absence of crystallographic data, the structural relationship of the two glutamic acids is unknown but an indication of their importance is their conservation in all the homologous proteins, including ovalbumin. The glutamic acid replaced in the S protein is in a predicted α-helical region[5] and in this way it resembles the mutation of the coincidentally named haemoglobin S. Both involve the introduction of a valine on the hydrophilic aspect of a helical region, the effect of which will be to favour intermolecular aggregation. Support for this is seen in the decreased stability of the *S* variant of α_1-AT[66]. This decrease in stability suggests that deficiency may be due to increased breakdown, although no gross difference has been detected between the half life of the S and that of the normal M protein[36]. The S protein does not accumulate in the liver and the problem is not apparently that of a failure of secretion, nor is it likely that a mutation of this type would affect translation rates. It is likely that the presence of the substituted valine results in incorrect folding of the nascent protein resulting in intracellular degradation and hence an apparent decrease in synthesis[5].

The *Z* mutation presumably acts in a different way to give a partial blockage in the processing of the protein. The sequence of the protein excludes some of the previously suggested mechanisms, that is, that the mutation might directly interfere with pre- or propeptide cleavage or with an oligosaccharide attachment site[3,37,67]. However, the sequence is of little help in suggesting alternative mechanisms. The mutation has occurred in a non-helical region but it must cause a perturbation in structure as the *Z* antitrypsin, like the *S*, has decreased *in vitro* heat stability[66]. The failure in processing of the polypeptide could be a consequence of this perturbation in structure; alternatively, it has been proposed[5] that it could be due to a misreading of the new Lys–Lys sequence 342–343 as a processing signal. No experimental evidence is available to support either proposal.

Conclusion

Knowledge of the structure of α_1-AT with other available information provides at least a partial outline of the pathophysiology of the function and dysfunction of the protein. In particular, it supports the previously proposed concept[6,7,59] that the emphysema associated with both α_1-AT deficiency and cigarette smoking is due to a protease–antiprotease imbalance. This understanding of the pathogenesis of the lung disease provides the basis for the design of therapy either by antiproteinase replacement or alternatively, by macrophage inhibition. One approach to replacement therapy is the development of low molecular weight analogues of the reactive centre of α_1-AT[42]. A more radical approach will be the use of recombinant DNA techniques to give a substitution of the reactive centre methionine to decrease lability and increase specificity for elastase. But the most useful therapy that follows from knowledge of the pathogenesis of the lung disease is the concise and effective counsel that can be given to the *PiZZ* individual: Don't smoke!

The detection of homozygous deficiency at birth is technically and logistically a simple task.[53] The problem is to devise a means of contacting affected individuals at adolescence, at a time when they can elect not to smoke and thus have a reasonable chance of a full and active life.

Internal rotation and gravitational quadrupole moment of the Sun

D. O. Gough

Institute of Astronomy, Madingley Road, Cambridge CB3 0HA, UK

The internal angular velocity of the Sun is estimated from observations of apparent rotational splitting of low-order low-degree global oscillations detected in fluctuations in the limb-darkening function. A sidereal rotation of 3 μHz is inferred for the deep interior; this is more than six times greater than the equatorial rotation frequency of the photosphere. The inferred angular velocity distribution does not vary strongly with latitude, and yields a gravitational quadrupole moment $J_2 \simeq 3.6 \times 10^{-6}$. When combined with the results of planetary radar observations to determine $(2-\beta+2\gamma)/3$, a combination of Eddington–Robertson post-newtonian parameters which in general relativity is unity, a value of about 0.994 ($\pm$0.012) is thus obtained.

ONE of the most important tests of theories of gravitation concerns the rates of precession of planetary orbits. In the fully conservative parameterized post-newtonian (PPN) formalism, for example, the predicted advance $\Delta\phi_0$ per orbital period of a planetary orbit with semi-major axis a and eccentricity e, after correcting for perturbations due to the other planets, is $6\pi GM\lambda_p/[a(1-e^2)c^2]$, where

$$\lambda_p = \tfrac{1}{3}(2-\beta+2\gamma) + \frac{R^2c^2}{2GMa(1-e^2)}J_2 \qquad (1)$$

Here M and R are the mass and radius of the Sun, G is the gravitational constant, c is the speed of light, and β and γ are Eddington–Robertson parameters of the PPN formalism[1,2]. In general relativity, for example, $\beta = 1$ and $\gamma = 1$, and hence $\frac{1}{3}(2-\beta+2\gamma) = 1$. The parameter J_2 measures the quadrupole moment of the Sun's gravitation field, normally presumed to arise from centrifugal distortion. It is defined such that the solar component of the gravitational potential outside the Sun, referred to spherical polar coordinates (r, θ, ϕ) with respect to the Sun's rotation axis, is

$$\Phi = \frac{GM}{r}\left[1 - J_2\left(\frac{R}{r}\right)^2 P_2(\cos\theta)\right] \qquad (2)$$

where P_2 is a Legendre function of second degree. Equation (1) was derived assuming the Sun's rotation axis to be perpendicular to the plane of the planetary orbit. The correction that should be made to account for the small tilt that exists is insignificant.

Since the contributions to $\Delta\phi_0$ from the quadrupole component of Φ and from the deviations from newtonian gravitation depend differently on $a(1-e^2)$, one should in principle be able to determine $\frac{1}{3}(2-\beta+2\gamma)$ and J_2 separately by combining observations of different planets. However, it has not been possible to do this, because the planetary precession rates are not yet known with adequate precision[3]. An independent measurement of J_2 is therefore required.

Attempts have been made to infer J_2 from the shape of the visible solar disk. The method relies on equating the oblateness E of the disk with that of the gravitational equipotentials, after accounting for the observed rotation of the photosphere and brightness inhomogeneities such as are produced by faculae. This yields $J_2 = \frac{2}{3}E$. It is interesting that modern observations have yielded quite different values: Dicke and Goldenberg[4] obtained

$$\tfrac{2}{3}E = (24.7 \pm 2.3) \times 10^{-6} \qquad (3)$$

whereas Hill and Stebbins[5] obtained

$$\tfrac{2}{3}E = (1.0 \pm 4.3) \times 10^{-6} \qquad (4)$$

The discrepancy has not been explained. Note, however, that the two measurements utilized different properties of the intensity distribution near the limb of the Sun, and that alone might prove to be the cause. Evidently one cannot infer J_2 until the discrepancy has been understood.

For the orbit of Mercury, equation (1) yields

$$\lambda_p = \tfrac{1}{3}(2-\beta+2\gamma) + 2.96 \times 10^3 J_2 \qquad (5)$$

Shapiro *et al.*[6], using radar measurements of the distance to Mercury, found

$$\lambda_p = 1.003 \pm 0.005 \qquad (6)$$

A similar analysis by Anderson *et al.*[3] gave

$$\lambda_p = 1.007 \pm 0.005 \qquad (7)$$

Shapiro *et al.* took J_2 to be equal to the value one calculates assuming the Sun to be rotating uniformly, which is 2×10^{-7} if the surface equatorial angular velocity is used, and thus arrived at a value for $\frac{1}{3}(2-\beta+2\gamma)$. It is evident from the uncertainty suggested by the difference between equations (3) and (4) that the passage from λ_p to the PPN parameters is premature.

The limitations imposed by the uncertainty in J_2 on the accuracy to which the precession data test theories of gravity has led to other proposals for probing the solar gravitational field. One method is to take advantage of the high eccentricity of Mercury's orbit to search for different periodic orbital variations. This would require tracking a spacecraft in orbit around Mercury. According to Anderson *et al.*[7] a precision of a few parts in 10^7 should be possible. Another suggestion is to track a spacecraft that passes by the Sun within a few solar radii[8]. Similar precision might be possible, though it could be affected by perturbations in Φ associated with long-period solar oscillations[9], especially if J_2 were as small as 2×10^{-7}. Preliminary calculations[7,10] suggest that J_2 could be measured to an accuracy

0028–0836/82/290334—06\$01.00

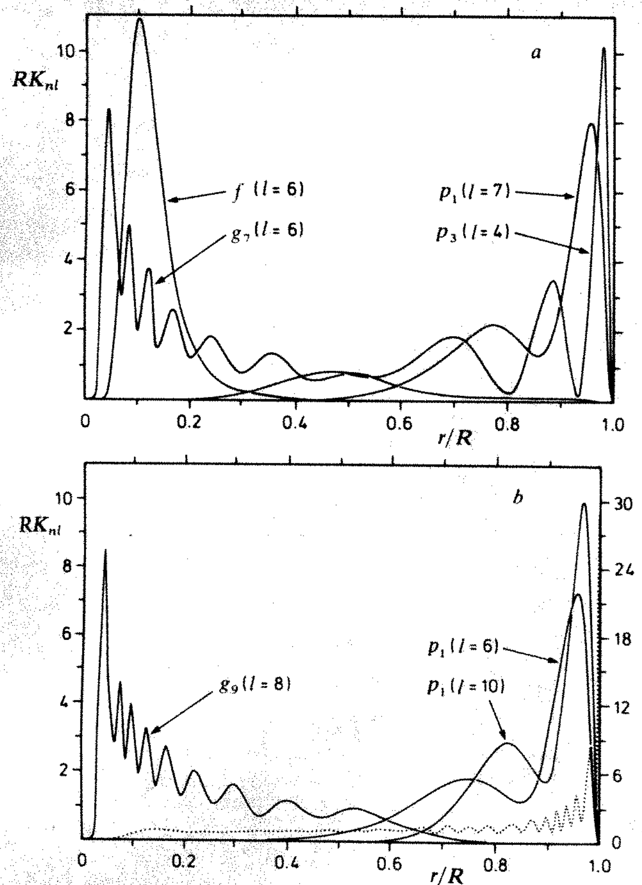

Fig. 1 Rotational splitting kernels RK_{nl} for the seven modes listed in Table 1. The dotted curve (to which the right-hand ordinate scale refers) is an average of the six kernels with $l=1$ and $l=2$ and frequencies closest to 2.5, 3.3 and 4.1 μHz. This is representative of the 5-min modes observed by Claverie *et al.*[25].

of a part in 10^8 if the spacecraft were in a bound orbit around the Sun.

The discovery of global solar oscillation by Hill and his collaborators[11], Severny *et al.*[12] and Brookes *et al.*[13] raised the possibility that the deep interior of the Sun could be measured more directly than had previously been possible[14]. In particular, rotational splitting of otherwise degenerate nonaxisymmetrical modes provides averages of the angular velocity Ω. Different modes weight Ω differently, and with a sufficient variety one can go some way towards determining the variation of Ω with position. I report here an attempt to estimate Ω from recent observations. This yields a preliminary rough estimate of the Sun's angular momentum, the rotational kinetic energy and J_2.

Properties of rotational splitting

Slow rotation causes nonaxisymmetrical standing wave patterns to precess about the rotation axis of the Sun. This is manifest as a splitting of the degeneracy in frequency with respect to the angular order m of the modes[15,16] (that is to say, the order m of the spherical harmonic that factors from the eigenfunctions). The splitting is an average of the angular velocity, weighted by a kernel that depends on the eigenfunction of oscillation of the nonrotating star. That kernel, which can be computed directly from the variational principle of Lynden-Bell and Ostriker[17], is discussed in refs 18–20. Here I assume that the solar angular velocity $\mathbf{\Omega}$ can be approximated by $\Omega\mathbf{k}$, where $\Omega(r,\theta)=\Omega_0(r)-\Omega_1(r)\cos^2\theta$ and $\mathbf{k}$ is a constant unit vector. In that case the cyclic frequency $\nu\equiv\nu_{nlm}$ of a mode of order n and degree l, with respect to an inertial frame of reference, is well approximated by $\nu_{nl}+\nu'_{nlm}$, where ν_{nl} is the corresponding frequency when $\Omega=0$, and

$$\nu'_{nlm}=\frac{m}{2\pi A}\int_0^R \rho\{\{(\xi-\eta)^2+[l(l+1)-2]\eta^2\}\Omega_0(r)$$

$$-[\![Q_{lm}\{(\xi-\eta)^2+[l(l+1)-7]\eta^2\}+\eta^2]\!]\Omega_1(r)\}r^2\,\mathrm{d}r \qquad (8)$$

$$\equiv\frac{m}{2\pi}\left\{\beta_{nl}\int_0^R K_{nl}(r)\Omega_0(r)\,\mathrm{d}r-\beta_{nlm}\int_0^R K_{nlm}(r)\Omega_1(r)\,\mathrm{d}r\right\} \qquad (9)$$

$$A=\int_0^R \rho[\xi^2+l(l+1)\eta^2]r^2\,\mathrm{d}r \qquad (10)$$

$$Q_{lm}\equiv\tfrac{1}{2}(2l+1)\frac{(l-|m|)!}{(l+|m|)!}\int_{-1}^{1}\mu^2[P_l^m(\mu)]^2\,\mathrm{d}\mu \qquad (11)$$

ξ and η, which depend on n and l but not on m, are measures of the radial and horizontal components of the adiabatic displacement eigenfunction $\delta\mathbf{r}$, defined in spherical polar coordinates by

$$\delta\mathbf{r}(\mathbf{r},t)=\mathrm{Re}\left\{\left[\xi(r)P_l^m(\cos\theta),\ \eta(r)\frac{\mathrm{d}}{\mathrm{d}\theta}P_l^m(\cos\theta)\right.\right.$$

$$\left.\left.im\eta(r)\,\mathrm{cosec}\,\theta\,P_l^m(\cos\theta)\right]\exp(im\phi-2\pi i\nu t)\right\} \qquad (12)$$

P_l^m is the associated Legendre function of the first kind, ρ is the equilibrium density of the Sun (which may be calculated ignoring the centrifugal distortion) and t is the time. The coefficients Q_{lm} can be expressed in terms of Gaunt integrals, which can be computed from the tables of Scott[21]. The factors β_{nl} and β_{nlm} are defined such that the kernels K_{nl} and K_{nlm} are unimodular (that is, their integrals are unity). Thus, if Ω_0 and Ω_1 were constant, the rotational perturbation ν'_{nlm} to the eigenfrequency would be $(m/2\pi)(\beta_{nl}\Omega_0-\beta_{nlm}\Omega_1)$.

If the latitudinal variation of Ω in the solar interior is no greater than the variation observed in the photosphere, then for p modes and low-order g modes of low degree, the second integral in equation (9) is considerably smaller than the first. Thus, since β_{nl} and K_{nl} are independent of m, the frequencies corresponding to the $2l+1$ possible values of m are approximately uniformly spaced.

Observations of apparent rotational splitting

Oscillations of the radial variation of intensity near the solar limb have been recorded by Bos and Hill[22]. Measurements were

Table 1 Rotationally split multiplets and the modes with which they have been identified

Multiplet	l_{min}	ν_c (μHz)	$\Delta\pm\sigma$ (μHz)	Mode	ν_{nl} (μHz)	$\beta_{nl}^{-1}(\Delta+\omega_e/2\pi)$ (μHz)
1	6	256.54	2.875±0.008	$g_7(l=6)$	258.8	2.945
2	8	260.38	2.902±0.006	$g_9(l=8)$	260.9	2.948
3	6	427.97	2.888±0.008	$f(l=6)$	425.6	2.958
4	6	471.10	0.96±0.02	$p_1(l=6)$	495.4	1.07
5	7	498.12	0.85±0.02	$p_1(l=7)$	518.7	0.94
6	10	592.65	0.74±0.01	$p_1(l=10)$	584.6	0.81
7	4	773.94	1.29±0.01	$p_3(l=4)$	759.2	1.39

The theoretical eigenfrequencies ν_{nl} are the frequencies ν_λ extrapolated from the frequencies ν_A, ν_B of models A and B of ref. 30 with $\lambda=1.26$. The corresponding frequencies of $f(l=32)$ and $p_2(l=10)$ are 588.5 and 780.1 μHz. Aside from possible errors in identification, the frequencies ν_c of the central components of the observed multiplets have standard error 0.07 μHz. The r.m.s. difference between ν_{nl} and ν_c is 13 μHz. Δ is the observed mean splitting, and σ is, according to Hill[24], a conservative estimate of the variation of the splitting with m. The last entry is numerically equal to the mean value of Ω_0, weighted by the appropriate kernel K_{nl} illustrated in Fig. 1.

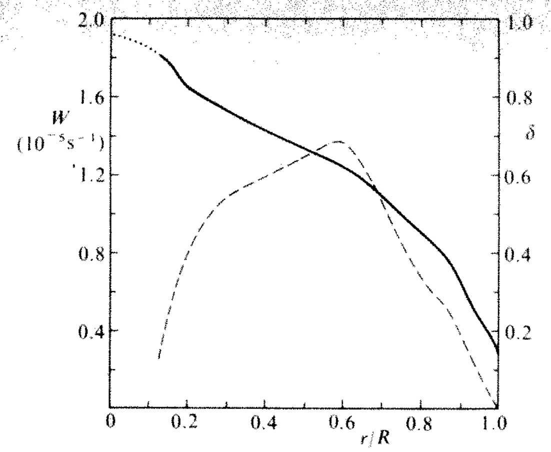

Fig. 2 Averages $W(r)$ of Ω_0 computed by the Backus–Gilbert optimal averaging procedure. Averaging kernels D with $\bar{r} < 0.12R$ cannot be constructed from the data kernels in Fig. 1, so W has been extrapolated to the origin with a cubic curve (dotted) that approximates W in the range $0.12 < r/R < 0.2$. Since $\mathscr{I}$ and $\mathscr{J}$ are both small near the origin (see Fig. 4), H, T, and J_2 are insensitive to the extrapolation procedure. The dashed line is the half-width δ of the averaging kernel D.

made simultaneously at three pairs of diametrically opposed locations, distributed symmetrically about the equator, and from them six functionals $\psi_i(t)$ of the limb-darkening function were constructed. For this discussion it does not matter how the functionals ψ_i are defined. It is necessary only to accept that their variation is produced by the ensemble of normal modes of oscillation of the Sun, whose frequencies are thus indicated by peaks in the power spectra of ψ_i. The solar origin of the signal is argued in refs 22, 23.

Observations of mean duration 9.3 h have been made on 18 days during a 41-day period[22]. Fourier transforms of $\psi_i(t)$ were computed, and from linear combinations of them power spectra of components of the oscillations satisfying certain symmetry relations could be isolated. For example, the power spectrum of $\sum_{i=1}^{6} \psi_i$ contains contributions from only those modes with even l and even m. Part of that spectrum is shown in ref. 22. Aliasing aside, the frequency resolution is 1/(41 day) = 0.28 μHz.

In the hope that the influence of the latitudinal variation of Ω on the splitting would be small, sequences of uniformly spaced peaks in the spectra were sought. Some care was taken to account for the side-bands imposed by the window function, but a systematic attempt to remove them was not made. To be acceptable, the spacing between the centres of the peaks was required to be uniform to 0.07 μHz. It is prudent to apply so stringent a condition, at least in a preliminary analysis, to guard against misinterpreting accidental sequences of peaks in the densely populated spectra. Seven sequences have been found. Their median frequencies ν_c, the mean frequency separations Δ and lower bounds $l_{\min}$ to l, inferred from the number of peaks in the sequences, were announced recently by Hill[24] and are reproduced in Table 1. For this investigation, I shall assume, with Hill, that these are sequences of rotationally split eigenfrequencies, and ask what that implies.

Before this analysis of the power spectrum, evidence of a mean rotational splitting of 0.75 μHz synodic in the low-degree 5-min oscillations was discovered by Claverie *et al.*[25]. The data are difficult to interpret because $2l+1$ components appear in the spectrum, whereas, owing to the symmetry of observing technique, only $l+1$ of the modes of degree l should be visible. Isaak[26] has suggested that the extra components are accounted for by an intense rotating magnetic field in the core of the Sun, as has been postulated by Dicke[27,28] to explain the 12.2-day variation in the Princeton oblateness data. However, it is not clear how that explains the 5-min oscillation data[29]. It is conceivable that a weak field could couple nearly resonant modes with different spatial symmetries, but in that case there is the danger that the coupling modifies the frequencies sufficiently to belie the apparent splitting that arises directly from rotation. Therefore a detailed account of the analysis that includes the 5-min modes will not be presented.

Identification of the modes

Tentative identifications were made by selecting those modes of the standard (nonrotating) solar model A of Christensen-Dalsgaard *et al.*[30] with l approximately equal to but not less than $l_{\min}$ whose frequencies are closest to the median frequencies of the groups of modes observed. It was borne in mind that if $l_{\min}$ underestimates l, as a result of failure to detect or recognize modes with $|m| = l$, the median frequency may differ from the frequency ν_{nl0} by an integral multiple of the frequency separation Δ. The identifications are listed in Table 1. In all cases $l = l_{\min}$.

It is important to realize that there is considerable uncertainty in the identification. This is true particularly of the multiplets 1–3 and multiplets 6 and 7. In the middle range there is less scope for error because the eigenfrequencies are more sparsely distributed.

Splitting kernels

Kernels $K_{nl}(r)$ are illustrated in Fig. 1 for the modes listed in Table 1. It is a property of all these modes that for given n and l the kernels K_{nlm} are nearly the same as K_{nl}. Therefore the kernels K_{nlm} are not displayed. This property also characterizes those other modes that might have been identified with the observed oscillations, and arises because the motion is nearly vertical wherever the amplitude of the mode is large.

It is immediately evident from Fig. 1 that the low-frequency modes sample mainly the rotation of the core, and the high-frequency modes the rotation near the surface. The greater values of Δ associated with the lower frequencies indicates immediately that the Sun's core is rotating more rapidly than the photosphere.

Latitudinal variation of Ω

Because, for the modes under consideration, $l(l+1)\eta^2$ is rather smaller than ξ^2, and $K_{nlm} \simeq K_{nl}$, the splitting formulae (8), (9) may be approximated by

$$\nu'_{nlm} \simeq \frac{m}{2\pi}\beta_{nl}(\bar{\Omega}_0 - Q_{lm}\bar{\Omega}_1) \qquad (13)$$

Table 2 Properties of estimates of Ω

Estimate	H	T	J_2	σ_Δ
1	5.0	25.7	3.6×10^{-6}	0.07
2	4.8	23.8	3.8×10^{-6}	0.01
3	5.3	31.5	4.3×10^{-6}	0
4	5.9	37.4	5.4×10^{-6}	0.04
5	5.4	31.3	4.1×10^{-6}	0.02
6	4.4	27.9	4.5×10^{-6}	0
7	1.0	3.8	1.4×10^{-6}	0

Estimate 1 is the result of the Backus–Gilbert inversion shown in Fig. 1. Estimates 2–5 are the curves 1–4 in Fig. 2. Estimate 6 is the seventh-degree polynomial in r with $\Omega(R) = \Omega_S$ that satisfies the splitting constraints (14) exactly. Estimate 7 is the function Ω_0 that minimizes J_2 and satisfies $\Omega_0(R) = \Omega_S$ and the splitting constraints (14). For any value J above the minimum J_2 there are infinitely many functions $\Omega(r)$ satisfying $J_2 = J$, the outer boundary condition and the splitting constraints (14). The entries σ_Δ are r.m.s. differences between Δ and the frequency splitting predicted by Ω_0, measured in units of the observed splitting Δ. The angular momentum H and the rotational kinetic energy T are measured in units of $I\Omega_S$ and $\frac{1}{2}I\Omega_S^2$ respectively, where $I \simeq 0.068MR^2$ is the moment of inertia of the extrapolated solar model about an axis through the centre. If the rotational splitting of low-degree 5-min modes claimed by Claverie *et al.*[25] is added to the data, the values of $10^6 J_2$ for the seven estimates of Ω listed above are 2.3, 2.1, 3.4, 2.9, 2.8, 14.4 and 1.4 respectively. In this case estimate 6 is the eighth-degree polynomial that satisfies the constraints. If the last two modes in Table 1 are replaced by $f(l=32)$ and $p_2(l=10)$, whose splitting kernels are somewhat more concentrated near the surface, the corresponding values of $10^6 J_2$ are 3.6, 2.1, 5.1, 5.9, 4.2, 438.4 and 1.2 when the 5-min datum is ignored, and 2.4, 1.7, 4.9, 2.9, 2.9, 790.3 and 1.2 when the 5-min datum is included.

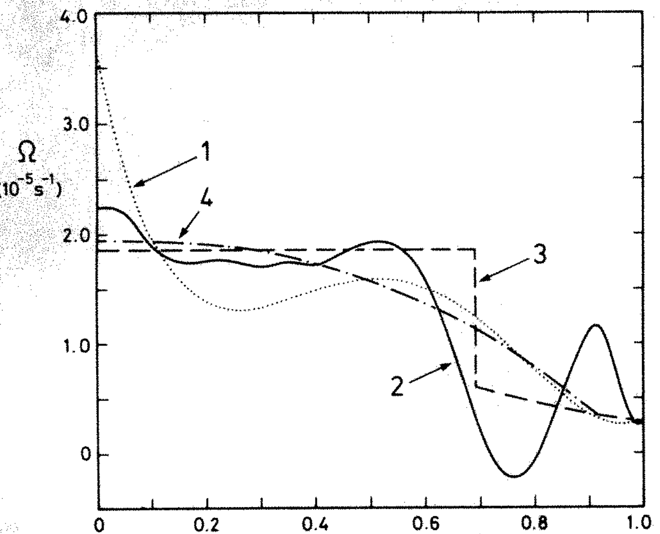

Fig. 3 Some possible rotation curves Ω_0 that are compatible with the data. Curve 1 is a fourth-degree polynomial and curve 2 minimizes the mean square gradient of Ω_0. Curves 3 and 4 vary inversely with r^2 for $r>r_c$; for $r<r_c$ curve 3 is constant whereas curve 4 is proportional to $1-\alpha(r/R)^b$. In each case the free parameters were chosen to fit to the constraints (14) by least squares, subject to curve 4 being continuous. Curve 2 satisfies (14) exactly. The data in Table 1 cannot distinguish between these curves.

where the overbar denotes the mean with weight K_{nl}. Thus from any observed nonuniformity in the splitting an estimate of $\bar{\Omega}_1/\bar{\Omega}_0$ may be obtained.

Nonuniformity in the splitting has several origins. Aside from observational error and differential rotation, the most likely source is a magnetic field. This can be distinguished from rotational splitting by a difference of symmetry. If, for example, $\nu^{\dagger}_{nlm}$ is the magnetic perturbation to frequency due to an axisymmetrical field, then $\nu^{\dagger}_{nl(-m)}=\nu^{\dagger}_{nlm}$, whereas $\nu'_{nl(-m)}=-\nu'_{nlm}$. This result holds even when the axis of symmetry does not coincide with the rotation axis, provided ν'_{nlm} is less than the width of the lines in the power spectrum. With sufficiently accurate data the two contributions could be separated.

It is a consequence of the different symmetries that ν'_{nlm} and $\nu^{\dagger}_{nlm}$ cannot cancel for all m. Therefore the deviations σ from uniform splitting listed in Table 1 can be used to estimate an upper bound to $\bar{\Omega}_1$. The standard deviation of the rotational contribution to the nonuniformity in the splitting can be computed easily from the approximation (13). If all detectable modes are present, the result, expressed in units of the mean splitting, varies monotonically from $0.32\bar{\Omega}_1/\bar{\Omega}_0$ to $0.40\bar{\Omega}_1/\bar{\Omega}_0$ as l varies from 4 to 10.

Consider first multiplets 4–7 in Table 1, whose kernels are concentrated near the surface of the Sun. The mean σ is about 0.015 of the mean splitting, which implies, if the modes have been identified correctly, that $\bar{\Omega}_1/\bar{\Omega}_0\leq 0.04$. This is to be compared with the differential rotation in the photosphere, which satisfies $\Omega_1(R)/\Omega_0(R)\simeq 0.2$. The result implies either that the θ-dependence of Ω is confined to a boundary layer about $0.05R$ deep, or that Ω_1 changes sign, so that at the base of the convection zone the rotation is faster at the poles than at the equator.

Note that among the surface modes, multiplets 6 and 7 are the more concentrated near the surface. Therefore one would expect their rotational splitting to be the less uniform, which is apparently not the case. Aside from the possibility that the data have been wrongly interpreted, this suggests either that the magnetic field increases with depth or that the modes have been incorrectly identified. According to equation (13), nonuniformity in the splitting increases as m increases, so it is quite conceivable that the components with the greatest values of m have not been recognized. The multiplet 6 could be a high-degree f mode, such as $f(l=32)$, and multiplet 7 could be $p_2(l=10)$. It is unlikely that multiplet 6 is a high-degree g mode, even though there are such modes with appropriate frequencies, because these modes are likely to be severely trapped beneath the convection zone and hence be unobservable[31,32].

Multiplets 1–3 in Table 1 are concentrated in the core. The high degree of uniformity observed in the splitting implies that the core's rotation is nearly uniform on spheres. The limits set by σ yield $\bar{\Omega}_1/\bar{\Omega}_0\leq 7\times 10^{-3}$. They also set limits on the magnetic field in the core. If a field of structure similar to that adopted by Dicke[27] is assumed, the mean field intensity is bounded above by about 3×10^4 G.

Radial variation of Ω

Because the contribution to ν'_{nlm} from Ω_1 is small, I shall neglect it. Then the mean observed splittings Δ listed in Table 1 yield seven differently weighted averages of Ω_0. These are

$$\int_0^R RK_{nl}(r)\Omega_0(r)\,\mathrm{d}(r/R)=\beta_{nl}^{-1}(2\pi\Delta+\omega_e) \qquad (14)$$

where ω_e is the orbital angular velocity of the Earth. The values of these averages are listed in Table 1.

Provided the data are not mutually inconsistent, inversion of equations (14) to obtain a plausible estimate of Ω_0 is possible, but not unique. Nonuniqueness arises partly because there are only a finite number of averages to constrain the function. Therefore one must adopt some criterion for preference. Here I follow an optimal averaging procedure of Backus and Gilbert[33]. For each value r_0 of r one attempts to construct a linear combination $D(r,r_0)=\sum\alpha_{nl}(r_0)K_{nl}(r)$ of the data kernels K_{nl} in such a way that D is concentrated near r_0. The α_{nl} are normalized to make D unimodular. The average $W(\bar{r})$ of Ω_0 weighted with the new kernel D is simply $\sum\alpha_{nl}\beta_{nl}^{-1}(2\pi\Delta+\omega_e)$. Here $\bar{r}$ is the median of D. If the attempt to concentrate D was successful, then D resembles a delta function, and one may safely set $\Omega_0(r)\simeq W(r)$. If D is not well concentrated, one may still adopt $W(r)$ as the least biased estimate of $\Omega_0(r)$, but one must bear in mind that structure on a scale smaller than the width of D cannot be resolved. Thus the function W is likely to be smoother than Ω_0. Moreover, it does not satisfy the constraints (14) precisely. Note, however, that W is an invariant property of data, in the sense that all functions $\Omega_0(r)$ that satisfy the constraints (14) have the same averages $W(\bar{r})$ when weighted with the averaging kernels D.

The Backus–Gilbert inversion procedure has been applied to the data listed in Table 1. In so doing, a further constraint of the form (14) was added, with a data kernel that is a delta function at $r=R$ and a right-hand side equal to $2\pi/(25.4\text{ days})=2.86\times 10^{-6}\,\mathrm{s}^{-1}\equiv\Omega_S$. This device ensures that $\Omega(R)=\Omega_S$. The function $W(r)$ is shown in Fig. 2.

To give an idea of the extent of the averaging, the half-width δ of D, defined as r_2-r_1 where

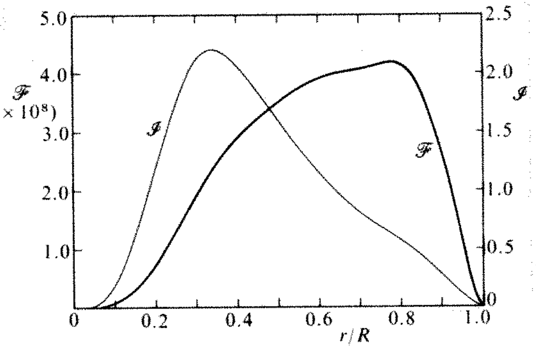

Fig. 4 The moment of inertia kernel $\mathcal{J}$ and the oblateness kernel $\mathcal{F}$, extrapolated linearly from the corresponding kernels of models A and B of ref. 30 as in equation (17) with $\lambda=1.26$. $\mathcal{J}$ is measured in units of the moment of inertia I, and $\mathcal{F}$ is measured in units of Ω_S^{-2}.

$$\int_{r_1}^{r} D\,\mathrm{d}r = \int_{r}^{r_2} D\,\mathrm{d}r = \tfrac{1}{4} \qquad (15)$$

is also displayed. The averages are quite well confined near the centre and the surface, but are very broad in the mid-range. This is not surprising, as none of the data kernels K_{nl} has a substantial amplitude where $0.2 \leqslant r/R \leqslant 0.8$. The failure of the Backus–Gilbert procedure to provide a kernel D that is well concentrated about any point in the mid-range results from a paucity of appropriate data, and does not reflect a deficiency in the procedure. Though $\Omega_0(r)$ is quite strongly constrained near the centre and the surface, there is a wide margin of uncertainty elsewhere.

An important goal of the inversion procedure is the attainment of a stable solution. If averaging kernels D are chosen so as to minimize δ, small changes to either the data or the kernels K_{nl} yield large changes in W when several different data, or linear combinations of them, provide nearly the same physical information. Thus errors are magnified and the solution is inaccurate. Backus and Gilbert[33] discuss how, at the expense of permitting somewhat broader averaging kernels D, a tradeoff between stability to errors in the data (or the mapping of those data on to Ω_0 via the data kernels K_{nl}) and formal mathematical accuracy can be achieved. That procedure has been adopted here. The rotation curve presented in Fig. 2 is stable to small changes in the data or the kernels, and is therefore more likely to be a good representation of the actual angular velocity of the Sun than is a curve constructed to fit the constraints (14) exactly.

As an indication of the uncertainty in $\Omega_0(r)$ I display four alternative possibilities in Fig. 3. The first is the fourth-degree polynomial in r satisfying $\Omega_0(R) = \Omega_S$ that best fits equations (14) by least squares. Its shape is quite sensitive to changes in the equilibrium solar model. (The corresponding seventh-degree polynomial, which is even more sensitive to the equilibrium model, satisfies equations (14) exactly. Some of its properties are listed in Table 2.) The second is in some sense the most slowly varying function that fits the data, for it minimizes the integral of $(\mathrm{d}\Omega_0/\mathrm{d}r)^2$ among all differentiable functions Ω_0 that satisfy the constraints (14) and $\Omega_0(R) = \Omega_S$. The third is of the form $\Omega_0 = \tilde{\Omega} =$ constant for $0 \leqslant r < r_c$ and $\Omega_0 = (R/r)^2\Omega_S$ for $r_c < r \leqslant R$. This function was chosen, somewhat arbitrarily, with the idea that the radiative interior might be rotating rigidly, aside from a thin boundary layer at the base of the convection zone. Because Ω_0 is very much smaller than the buoyancy frequency in the radiative zone, only a slight smoothing of the discontinuity would be necessary to satisfy the Solberg–Høiland dynamical stability criterion[34–36] in the equatorial plane, with negligible effect on the values of the angular momentum, rotational kinetic energy and J_2. Again the free parameters were chosen to give the closest fit to equation (14) by least squares, yielding $r_c = 0.69R$ and $\tilde{\Omega} = 1.86 \times 10^{-5}\,\mathrm{s}^{-1}$. The value of r_c is close to independent modern estimates[37–40] of the radius of the base of the convection zone. The fourth function is of the form $\Omega_0 = \tilde{\Omega}[1 - \alpha(r/R)^b]$ for $0 \leqslant r \leqslant r_c$ and $\Omega_0 = (R/r)^2\Omega_S$ for $r_c \leqslant r \leqslant R$, with $\tilde{\Omega}$, α, b, r_c chosen to give the least squares fit to equation (14) subject to Ω_0 being continuous.

Angular momentum, rotational kinetic energy and J_2

From each of the rotation curves displayed in Figs 2 and 3 it is straightforward to compute the angular momentum H, the rotational kinetic energy T and the measure J_2 of the gravitational quadrupole moment. These are given by

$$H \simeq \int_0^1 \mathscr{I}\Omega_0\,\mathrm{d}x, \qquad T \simeq \tfrac{1}{2}\int_0^1 \mathscr{I}\Omega_0^2\,\mathrm{d}x, \qquad J_2 \simeq \int_0^1 \mathscr{F}\Omega_0^2\,\mathrm{d}x \quad (16)$$

where $x = r/R$, $\mathscr{I}(x) = (8\pi/3)R^5\rho x^4$ and $\mathscr{F}$ is given in ref. 17. The results are listed in Table 2. The kernels $\mathscr{I}$ and $\mathscr{F}$ are displayed in Fig. 3. Notice that they are greatest where knowledge of Ω_0 is the least. This unfortunate property magnifies the undertainty in H, T and J_2.

On the solar helium abundance

A least squares fit of the frequencies

$$\nu_\lambda = \lambda\nu_A + (1-\lambda)\nu_B \qquad (17)$$

interpolated or extrapolated linearly from the eigenfrequencies ν_A and ν_B of models A and B of ref. 30 (which have initial helium abundances $Y = 0.25$, 0.19 respectively) to observed frequencies of low-degree 5-min modes[38] yields $\lambda = 1.36 \pm 0.12$. Thus it seems that Y is somewhat greater than 0.25. A similar fit to the frequencies in Table 1 yields $\lambda = 1.26 \pm 0.79$. The latter fit is hardly strong independent evidence that $Y > 0.25$, especially since the mode identifications are uncertain. Nevertheless, it does show that the data in Table 1 are apparently consistent with this result. All the computations listed in this paper used the extrapolated model with $\lambda = 1.26$. Using model A typically changes H^2, T and J_2 by no more than 10%.

Conclusion

If the sequence of peaks found in the spectra of Bos and Hill[22] really are a consequence of rotational splitting, then it may confidently be concluded that the central core of the Sun rotates on average some six times faster than the surface. Moreover, the angular velocity Ω in the core is almost independent of latitude. The distribution of angular velocity throughout the rest of the Sun is uncertain, but it is not unlikely to resemble the solid curve in Fig. 2. Of course, there may be variations about that curve on a scale less than δ (shown also in Fig. 2). Such structure cannot possibly be resolved by observations of only the modes listed in Table 1, however precise the measurements. What is needed is to observe modes with data kernels that have substantial amplitudes where $0.2 \leqslant r/R \leqslant 0.8$.

Aside from a smoothed version of curve 3 in Fig. 3, none of the estimates of Ω_0 is dynamically stable. All the estimates are unstable to the Rayleigh criterion $\mathrm{d}(\varpi^2\Omega_0)^2/\mathrm{d}\varpi > 0$, where ϖ is the distance from the rotation axis. This condition is relevant when thermal diffusion is taken into account[41–43]. Indeed, it is interesting that there exists no function Ω_0 satisfying $\Omega_0(R) = \Omega_S$ and the Rayleigh criterion that can reproduce the frequency splitting of multiplets 4–7 in Table 1. Therefore the data seem to imply either that the mean flow is stabilized by some agent, such as a magnetic field, or that the natural tendency of the instability to restore Ω_0 to a state satisfying the Rayleigh criterion is effectively countered by some other angular-momentum transporting process.

The splitting data alone cannot determine Ω_0. Thus, to arrive at an estimate it is necessary to impose at least one additional restriction. That chosen here is one of smoothness, and was applied by equating the solid curve in Fig. 2, which is a well-determined average of Ω_0 with a known kernel D, with Ω_0 itself. This procedure has been applied successfully in other inverse problems, particularly in geophysics. The result is likely to be smoother than the actual angular velocity.

The curve depicted in Fig. 2 implies that the measure J_2 of the gravitational quadrupole moment is 3.6×10^{-6}. It is difficult to judge how accurate this value is, partly because the identification of the modes is uncertain, and partly because even if the modes were known, the constraints imposed by the splitting alone do not restrain the possible functions Ω_0 within tight bounds. The smallest value of J_2 compatible with the data is about 1.2×10^{-6}; the data cannot bound J_2 above.

The implications the estimate has on the test of gravitation theories using the precession of the orbit of Mercury can be assessed from equations (5)–(7). Taking $J_2 = 3.6 \times 10^{-6}$ yields

$$\tfrac{1}{3}(2 - \beta + 2\gamma) = \begin{matrix} 0.992 \pm 0.005 & \text{(ref. 6)} \\ 0.996 \pm 0.005 & \text{(ref.3)} \end{matrix} \qquad (18)$$

The errors quoted are standard errors arising from the orbit analysis, and take no account of the uncertainty in J_2.

Finally, it should be remembered that a careful analysis of the power spectra has yet to be undertaken, and that the uniformly spaced sequences of peaks might have been interpreted wrongly.

I thank Professor H. A. Hill for collaboration in Cambridge last November when together we isolated some of the multiplets in the power spectrum, identified the modes of oscillation, constructed a crude rotation curve and made our first estimate of J_2. Since then our opinions about the implications of the data have diverged, and we have decided to publish our findings separately (see ref. 44). I thank J. Christensen-Dalsgaard for some computer programs and comments, and D. Gubbins, D. Lynden-Bell and K. Whaler for discussions, also J. E. Pringle for suggesting improvements on an early version of the paper.

The thermal springs of Bath

Geochemical and hydrogeological evidence shows that the thermal springs at Bath originate from the Mendip Hills. A maximum subsurface temperature of 80 ± 16 °C is attained during circulation to between 2.7 and 4.3 km within the Carboniferous Limestone. The residence time of the bulk of the water is < 10,000 yr.

INTEREST in the evaluation of the geothermal resources of Britain has prompted a thorough geochemical investigation of the Bath thermal springs and their regional setting[1]. The King's Spring, the principal spring at Bath, emerges through Lower Lias shales within a reservoir of Roman construction. It has a flow of 13 l s^{-1} at a temperature of 46.5 °C which records show to have been constant within ±0.5 °C since 1754. Its thermal yield above a non-thermal groundwater temperature of 10 °C is 2.0 MW. Two smaller springs at Bath, the Cross Bath and Old Royal springs, have chemical compositions very similar to that of the King's Spring. Thermal water also occurs at Bristol where the Hotwells Spring discharges from Carboniferous Limestone into river muds just above low tide level in the Avon gorge. The flow is about 0.2 l s^{-1} at 24 °C and the thermal yield is only 7 kW.

The Bath/Bristol district is a complex synclinal structure formed between three intersecting fold axes[2]. The most important aquifers which might contribute to the flow of the thermal water, are in the Carboniferous Limestone and in Triassic deposits. The Old Red Sandstone (Devonian) and the Pennant Sandstones (Carboniferous) have only restricted hydraulic continuity.

The origin and composition of the Bath thermal waters have been the subject of much scientific curiosity. Notable associated discoveries include the extraction of helium from the exsolved gases by Sir James Dewar[3]; the identification of their radioactivity due to radium by Strutt[3] in 1904 and that due to radon by Munro[4] in 1928. However, no acceptable explanation of the heat source and circulation history of the waters has yet been proposed. The objective of the present study was to use a range of geochemical techniques to deduce the source, the circulation history, the temperature at depth and the age of groundwater[5].

Geochemical characteristics

(1) Inorganic chemistry: the King's Spring water has a total mineralization of 2,150 mg l^{-1} and Ca^{2+} and SO_4^{2-} are the dominant ions (Table 1). The chemical composition remained constant over the 2 yr period of investigation, and comparison with earlier work[6–9] suggests that the composition is stable over a long period. This stability is also reflected in the fact that the thermal water is in equilibrium with the minerals calcite, dolomite, gypsum, fluorite and barite as calculated using the WATEQF program[10].

Regional sampling of representative groundwaters from local aquifers was carried out and these results[5] show that no other groundwaters with a composition similar to that of Bath thermal water are found in the region, except locally in the Triassic aquifer, as discussed below. The Hotwells spring at Bristol has a composition equivalent to a mixture of Bath-type thermal water and shallow, Carboniferous Limestone water in the ratio 1 : 2.3.

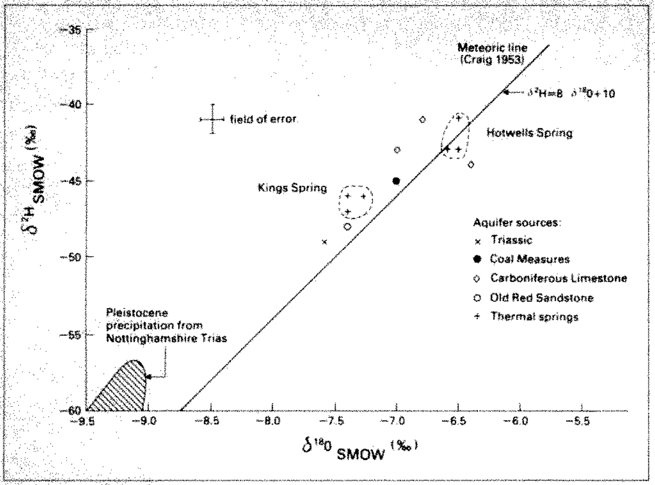

Fig. 1 Plot of hydrogen and oxygen stable isotope results for the thermal waters in relation to other groundwaters in the region.

(2) Dissolved radioelements: The isotope ^{234}U can be dissolved in preference to its precursor, ^{238}U, as a consequence of its genesis by decay processes and the $^{234}U/^{238}U$ activity ratio in groundwaters is frequently in excess of equilibrium[11]. The Bath thermal water is distinguished from other groundwaters in the region by a very low U-content and a high $^{234}U/^{238}U$ activity ratio (Table 1*c*). Only groundwaters from the Old Red Sandstone have similar activity ratios although they generally have higher U-contents than thermal water.

The high level of radioactivity in the King's Spring water is due to ^{222}Rn and during 1977 it gradually increased from 1,000 to 2,220 pCi kg^{-1}, the value determined[12] in 1972. This increase is attributed to a delayed piezometric recovery following the unusual drought conditions of 1976. Other radiochemical parameters and the radiogenic ^4He content similarly increased during 1977. ^{222}Rn contents similar to that of the King's Spring also occur locally in groundwaters from the Trias. Although the ^{226}Ra activity in the water is much lower than that of ^{222}Rn, it is the most significant radioelement present with regard to radiological hazard[13]. The short-lived β-emitting ^{222}Rn daughters, $^{214}Pb/^{214}Bi$ are present in equilibrium with ^{222}Rn. The isotope ^{210}Pb (half life 22 yr) requires about 100 yr to reach equilibrium with a constant ^{222}Rn source. Because the activity of ^{210}Pb in the thermal water is negligible although there is adequate natural Pb carrier present, this suggests either that the ^{222}Rn content has not been constant for a long period or that rapid wall-rock exchange of lead isotopes must be occurring.

The natural Th content of the King's Spring is below the detection limit of 0.002 µg per kg. The β-emitting ^{232}Th daughters, $^{212}Pb/^{212}Bi$, are present to the extent of 2.6 pCi kg^{-1}. These isotopes must be derived by ^{220}Rn release into the groundwater by mechanisms similar to those for ^{222}Rn release. The ratio of $^{222}Rn/^{220}Rn$ activities suggests that the U/Th ratio in the source rock could be as high as 250:1, though this may be an overestimate as the efficiency of ^{220}Rn release could be much less than that for ^{222}Rn. However, the uranium geochemistry also suggests that U deposition has occurred somewhere in the flow system.

(3) Dissolved gases: The gas composition (Table 1*d*) can be explained as the exsolution of atmospheric gases, which were dissolved at recharge, modified by the geochemical reaction of oxygen in the aquifer, by the addition of radiogenic ^4He due to radioelement decay and by the addition of hydrocarbon gases. At atmospheric pressure, the ratio of nitrogen solubility at 46.5 °C to that at 9.5 °C, the approximate recharge temperature, is 0.6, so that less than half of the dissolved gas should be exsolved as the thermal water re-equilibrates with the atmosphere. The total dissolved gas flow was calculated as 710 l h^{-1} in the present study and this may be compared with estimates[14] of the total exsolved gas flow of 208 l h^{-1}. Seasonal fluctuations

in dissolved oxygen (<0.5–6.0 mg l^{-1}) and in *Eh* (redox potential) were also noted and may indicate some mixing of waters at intermediate depths.

Source of thermal groundwater and its recharge

The hydrogen and oxygen isotopic compositions of the thermal water demonstrate that it is of meteoric origin (Fig. 1). The isotopic compositions lie close to the worldwide meteoric line[15] and the ratios are similar to those of modern shallow groundwaters in the region. The Bath thermal water may be clearly distinguished from known occurrences[16] of late Pleistocene groundwater elsewhere in England where a recharge temperature some 5 °C cooler than postglacial climatic conditions has been indicated. The ratios of dissolved atmospheric inert gases in the thermal waters indicate recharge temperatures around 9 °C. The combined evidence shows that climatic conditions at recharge were similar to those of the present day.

The piezometric levels in the various aquifers in the Bath/Bristol region are shown in Fig. 2. The piezometric level of the King's Spring is known from the historical record for a well which encountered thermal water in Kingsmead Street[17] in 1836. It is 40 m above sea level (10 m above the elevation of the spring). The only location with sufficient head to cause flow at the King's Spring is the Mendip Hills, about 15 km to the south-west and on the margin of the basin.

Maximum temperature and circulation depth

Rock–water equilibration temperatures for groundwaters from geothermal areas have been estimated from the amounts of dissolved Na^+, K^+, Ca^{2+} and SiO_2 (refs 18, 19). It was found that the cation geothermometers were not valid for the sedimentary formations of the Bath/Bristol region. The application of the SiO_2 geothermometer depends on which silica polymorph controls its dissolution. The thermal groundwaters are closer to equilibrium with chalcedony ($SI = +0.18$) than with quartz ($SI = +0.60$) but because of the limited number of springs the control on SiO_2 solution is uncertain. Maximum rock equilibration temperatures of 64 °C (for chalcedony control) and 96 °C (for quartz control) have been calculated and the maximum temperature reached at depth probably lies within this range. The SiO_2 geothermometer indicates that the thermal component of the Hotwells source has been equilibrated in the range 49–72 °C before subsequent mixing with shallow groundwater from the Carboniferous Limestone.

The necessary circulation depth for meteoric water to reach these temperatures may be estimated from the geothermal gradient. The only geothermal gradient measurement[20] (11 °C km^{-1}) in the basin, however, is known to have been affected by cold water inflows in the borehole. On the assumption that the region is one of average heat flow (40 mW m^{-2}), a geothermal gradient close to 20 °C km^{-1} is more likely (J. R. Bloomer, personal communication). This would place the circulation depth of the Bath thermal water in the range 2,700–4,300 m to attain a temperature of 64–96 °C and this depth strongly implies that either the Carboniferous Limestone and/or the Old Red Sandstone must be the principal storage aquifer(s)

The slightly negative $\delta^{13}C$ (−1.5‰) of the dissolved bicarbonate is very strong evidence that the thermal water has equilibrated chemically with the marine Carboniferous Limestone rather than with the largely non-marine Old Red Sandstone. The value of $\delta^{13}C$ for the latter[21] is −10.7‰ and is too negative to permit the development of the observed $\delta^{13}C$ of the thermal water. It must be concluded that the most recent storage and chemical equilibration of the carbonate system takes place within the Carboniferous Limestone ($\delta^{13}C = -0.05$‰), although a proportion of the thermal water may previously have been transmitted in the Old Red Sandstone.

Thermal water age

Tritium, ^3H, produced by thermonuclear weapon testing, was used to identify any post-1950s recharge. The ^3H content of the King's Spring averaged 1 ± 2 TU over the monitoring period and the highest observed value was 3.1 ± 2 TU. This, together with the small amounts of nitrate present, variations in dissolved O_2, *Eh* and $^{234}U/^{238}U$ activity ratio, suggests that there could be some mixing of the thermal water with very small quantities of 'recent' waters from shallow aquifers.

The ^{14}C specific activity for the dissolved bicarbonate of the King's Spring averages 4.5% of that for modern carbon (Table 1*c*). The uncertain source and age of any 'young' mixing component leads to uncertainty in the interpretation of the carbon isotope data in terms of residence time for the thermal water. Assumptions about the extent of mixing, however, allow limiting conditions to be defined. If there is no mixing with recent groundwater, and the ^{14}C activity represents that remaining after decay of the original ^{14}C present, a corrected age for the thermal water of 20,000 yr may be derived on the basis of the stoichiometric reaction between biogenic CO_2 (100% modern carbon; $\delta^{13}C - 26.1$‰) and ^{14}C- dead carbonate in the recharge zone (no ^{14}C; $\delta^{13}C$ −0.05‰ for Carboniferous Limestone). Such a 1 : 1 reaction between carbonate and biogenic CO_2, however, would result in a $\delta^{13}C$ value of −13.0‰ for the dissolved bicarbonate.

The measured $\delta^{13}C$ of the thermal water bicarbonate (Table 1*c*) is −1.6‰, and this indicates that extensive bicarbonate/carbonate interphase exchange has occurred after the initial congruent solution of carbonate. It is not possible to estimate, or correct for, the concurrent loss of ^{14}C from the bicarbonate in solution to the aquifer carbonate in this process. The age estimate of 20,000 yr is therefore a maximum possible age, provided that no ^{14}C activity has been introduced by mixing with shallow groundwater of recent origin. Alternatively, if mixing with recent groundwater (which may be dead to ^3H, but contain appreciable ^{14}C) is sufficient to account for all the observed ^{14}C activity, then the thermal water itself is dead to ^{14}C and is older than 50,000 yr.

Fig. 2 Outcrop and subcrop of Palaeozoic strata in the Bath–Bristol region, with major structural features (after G. A. Kellaway, unpublished data); the localities sampled during the study and the piezometric data are also shown.

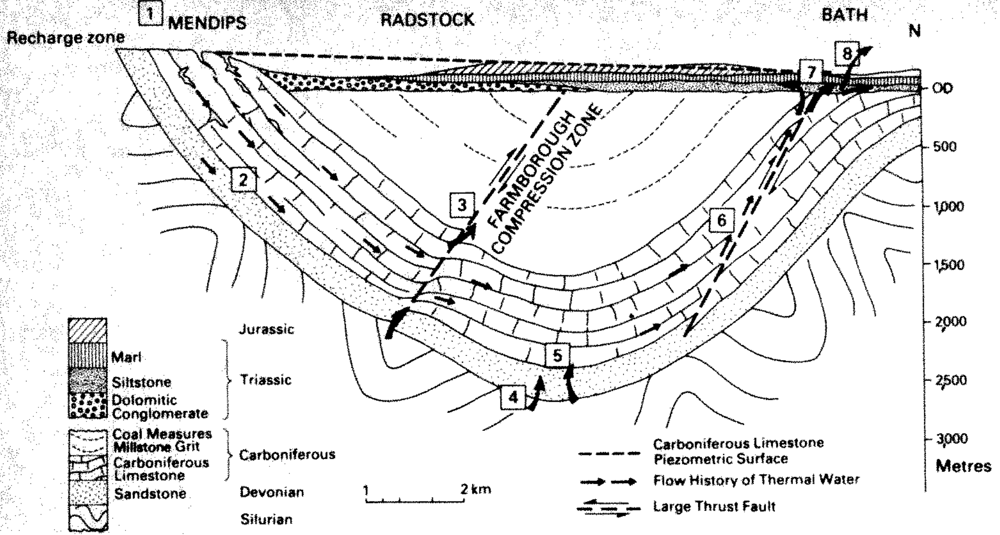

Fig. 3 Conceptual model of the flow path of thermal water in the Bath–Bristol Basin: 1, recharge (9–10 °C) at the Carboniferous Limestone/Old Red Sandstone outcrop; 2, down dip and down gradient flow, assisted by karstic development; 3, possible gain from Lower Palaeozoics and leakage to Upper Carboniferous via Farmborough compression zone; 4, some leakage of very old ^{4}He-bearing groundwater from Old Red Sandstone and possibly Lower Palaeozoics; 5, storage and chemical equilibration within the Carboniferous Limestone, at 64–96 °C; 6, relatively rapid ascent along thrust fault system; 7, some recharge of Triassic by thermal water at Bath; 8, discharge of the thermal springs at Bath (46.5 °C).

The temperature at which the thermal water was recharged (9–10 °C), estimated from its inert gas contents and its isotopic composition (δ^2H and δ^{18}O), shows that recharge took place in climatic conditions similar to those of the Holocene. This implies either that the water is younger than 10,000 yr (the beginning of the present climatic optimum), or older than 70,000 yr (the end of the last interglacial). It is therefore not possible to distinguish between the alternative explanations for the ^{14}C activity in the water, on the basis of its recharge temperature.

The ^{4}He content of a groundwater increases with its residence time in a formation of porosity, ϕ, and density, ρ, according to the equation[22]:

$$^4\text{He content, cm}^3/\text{cm}^3\ \text{H}_2\text{O} = \rho\,\phi^{-1}\,\{1.19\times10^{-13}\,[\text{U}]+2.88\times10^{-14}\,[\text{Th}]\}t \qquad (2)$$

where [U] and [Th] are the U and Th contents of the aquifer rock and t is the groundwater age in years if all the ^{4}He generated is dissolved in the pore fluids. This equation is not strictly applicable to the Carboniferous Limestone which is a fracture-flow system for which estimation of effective porosity is difficult. It is also unlikely that all the ^{4}He generated would be dissolved in the fracture fluids if the porosity is low. However, equation (2) yields a minimum age of 250,000 yr for a porosity of 1% and the radioelement contents of the Carboniferous Limestone. The Old Red Sandstone has radioelement contents about four times higher than those of the Carboniferous Limestone and for a similar porosity the minimum residence time to generate the ^{4}He in this formation is 60,000 yr. The generation of the observed ^{4}He content of the thermal water, within the Carboniferous Limestone, it is impossible for a residence time as short as 10,000 yr. At least a proportion of the thermal water must be much older and may be derived from the Old Red Sandstone.

Hydraulic controls and local conditions

The thermal water probably rises at Bath by way of a southerly-dipping east–west thrust fault in the vicinity. During the artesian flow of thermal water in Kingsmead Street[17], it was noted that an immediate and considerable decrease in flow occurred at the King's Spring and at the Cross Bath and Old Royal Springs. This indicates that the storage capacity of the Trias cannot be large. It was found that groundwaters which are chemically similar to Bath thermal water occur in the Trias at up to 2 km from the King's Spring. It therefore appears that the rising thermal water, under pressure, is recharging the Triassic sequence, probably by way of the Palaeozoic unconformity. This suggestion is supported by the available piezometric data (Fig. 1).

Limits on the likely hydraulic gradient between the Mendips and the Bath Spring are set by the level of the perennial discharge springs to the north of the pericline and the maximum level of the water table on Mendip. For a first approximation, a hydraulic gradient of 0.005 appears likely. Applying Darcy's law to the flow rate at Bath for an estimated cross-sectional area perpendicular to the direction of flow of 7×10^5 m^2 (the Carboniferous Limestone being ~700 m thick over a 1 km segment), the effective permeability controlling the flow of thermal water at depth is calculated as ~0.3 m day^{-1}. This is reasonably lower than the permeability to diffuse flow of 4 m day^{-1} in the Mendip Carboniferous Limestone outcrop[23]. For an effective porosity between 1 and 10%, volumetric considerations suggest the actual flow velocity would be between 0.1 and 0.01 m per day. Up to 4,000 yr would therefore be required to traverse the 15 km betweeen Mendip and Bath.

Discussion

The thermal water at Bath has very constant chemical and thermal characteristics. It is of meteoric origin, and was recharged in climatic conditions similar to those in the Holocene. Recharge probably takes place on the Mendips, where sufficient elevation provides the piezometric head controlling the flow across the basin. The Carboniferous Limestone acts as the last important storage aquifer for the thermal water where it equilibrates chemically and thermally at a depth of between 2,700 and 4,300 m at a temperature in the range of 64–96 °C, before relatively rapid ascent to the spring discharge points. At Bath, the thin Triassic aquifer which overlies the Palaeozoic unconformity is recharged by the rising thermal water but the major proportion discharges at the King's Spring through the Lower Lias. Although various techniques have been used to try to determine its residence time no unambiguous estimate can presently be made.

Although the hydraulic model is simplistic, it is in order of magnitude agreement with the conclusion that the bulk of the thermal water is <10,000 yr old and on balance we favour this interpretation. To account for the observed level of ^{4}He, this implies that a small proportion of the thermal water must have an extremely long residence history, probably in the Old Red Sandstone, before chemical re-equilibration in the Carboniferous Limestone.

Implications for geothermal development

At the King's Spring, Bath, a discharge of almost 50 m^{3}h^{-1} of water at 46 °C results from a natural head loss of 10 m. A pumped drawdown of 30 m in a borehole tapping the resource at depth might therefore provide a supply of 100–110 m^{3}h^{-1}. If the actual discharge were at 70 °C and the water were rejected from a heat exchanger at 25 °C, this would give a thermal yield of about 5 MW. The use of a heat pump would increase the thermal yield.

It is probable that the Carboniferous Limestone stores thermal water elsewhere along its 15-km strike between Bath and

Bristol. This is, however, only speculation and could only be proved by exploratory drilling.

It may be possible to exploit thermal groundwater stored in the Triassic aquifer at Bath without the need for wildcat drilling in the Carboniferous Limestone. The low effective bulk permeability of the Carboniferous Limestone at depth, however, is unlikely to support a flow of thermal water (across a 1 km wide section) much greater than the natural flow at the Bath springs. There could, therefore, be no exploitation of thermal water within a radius of several kilometres from Bath without risk of seriously affecting the spring discharge. The hydrogeological conditions at Bath must be thoroughly investigated before any such development, if the intrinsic historical and tourist value of the springs is to be protected.

We thank the City Councils of Bath and Bristol for permission to carry out work at the springs and for their assistance during sampling, the Wessex Water Authority for their collaboration in the regional groundwater sampling, and local landowners for providing access. We particularly thank colleagues at the IGS for analytical work and considerable help both during the sampling and in discussion of the results. We also acknowledge the help of SURRC, East Kilbride and AERE, Harwell for providing the radiocarbon and tritium analyses. We thank Dr G. A. Kellaway for valuable discussions concerning the geology of the region. The work was funded partly by the U.K. Department of Energy and the EEC under research contract 084–76–EG(UK) and partly by NERC research grand GR3/2622A. It is published with permisssion of the Director, Institute of Geological Sciences (NERC).

T24 human bladder carcinoma oncogene is an activated form of the normal human homologue of BALB- and Harvey-MSV transforming genes

Eugenio Santos, Steven R. Tronick, Stuart A. Aaronson, Simonetta Pulciani & Mariano Barbacid

Laboratory of Cellular and Molecular Biology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

A transforming gene isolated from T24 human bladder carcinoma cells is closely related to the BALB murine sarcoma virus (MSV) onc *gene (v-*bas*). This transforming gene is localized to a 4.6 kilobase pair (kbp) region and is expressed as a 1.2-kbp polyadenylated transcript, which contains v-*bas *related sequences. Moreover, antisera known to detect the immunologically related* onc *gene products of BALB- and Harvey-MSVs recognized elevated levels of a related protein in T24 cells. The normal human homologue of v-*bas *was found to be indistinguishable from the T24 oncogene by heteroduplex and restriction enzyme analysis. These results imply that rather subtle genetic alterations have led to the activation of the normal human homologue of v-*bas *as a human transforming gene.*

THE genetic alterations that cause normal cells to become malignant in natural conditions are for the most part still obscure. A potentially important approach towards understanding such mechanisms has come from studies of acute transforming retroviruses. It is now well established that the majority of these viruses possess substituted viral genes necessary for replication with a discrete segment of host genetic information[1]. When incorporated within the retroviral genome, such transduced cellular (*onc*) sequences acquire the ability to induce neoplastic transformation. At least 24 independent acute transforming retrovirus isolates have been found to date, of which some contain the same or closely related *onc* genes[2–7]. These findings have suggested that vertebrates contain a limited number of cellular genes that can acquire transforming properties when recombined with retroviral sequences.

The development of DNA-mediated gene transfer techniques has recently made it possible to identify transforming genes in a variety of tumours, including some of human origin[8–19]. DNAs isolated from either naturally occurring human tumours or from human tumour cell lines, have been shown to induce morphological transformation when transfected into suitable assay cells[12–19]. In fact, a transforming gene has been isolated by molecular cloning techniques from the T24[20] and EJ[21] human bladder carcinoma cell lines[19,22,23]. Preliminary characterization of this bladder carcinoma oncogene has revealed it to be of human origin and small size (less than 6 kilobase pairs (kbp))[19,22,23]. We undertook the present studies to investigate whether this human bladder carcinoma oncogene was related to any of the cell-derived *onc* sequences that have acquired neoplastic properties on transduction into retroviruses.

A human bladder carcinoma transforming gene is related to v-*bas*

The availability of a molecularly cloned bladder carcinoma transforming gene, designated the T24 oncogene, enabled us to examine its relationship with the *onc* genes of a variety of

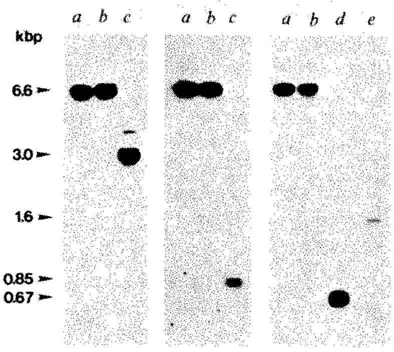

Fig. 1 Relationship between the T24 oncogene and the retroviral *onc* genes of BALB-MSV (v-*bas*) and of MC29 virus (v-*myc*). Molecularly cloned DNAs, including 100 ng of a 6.6-kbp *Bam*HI fragment containing the T24 oncogene, purified from λT24-15A DNA[19] (*a*), 100 ng of a 6.6-kbp *Bam*HI fragment containing the T24 oncogene purified from pT24-C3[32] (*b*), 200 ng of the above 6.6-kbp *Bam*HI fragment but digested with *Sac*I (*c*), 100 ng of 0.67-kbp *Hin*dIII to *Bam*HI fragment of v-*bas* (*d*), and 200 ng of 1.6-kbp *Sac*I to *Bam*HI fragment of v-*myc* (*e*), were electrophoresed in horizontal agarose (1% w/v) gels, blotted to nitrocellulose filters and hybridized in stringent conditions (50% formamide, 5×SSC and 42 °C) for 16 h to 5×10^6 c.p.m. of the following nick-translated probes: *A*, ^{32}P-labelled 0.67-kbp *Hind* III to *Bam*HI v-*bas* DNA; *B*, ^{32}P-labelled 1.6-kbp *Sac*I to *Bam*HI v-*myc* DNA; *C*, ^{32}P-labelled 6.6-kbp *Bam*HI T24 oncogene DNA, as described previously[42]. Hybridized blots were exposed to Kodak XR-5 film at −70 °C in the presence of intensifier screens for 4 h (*A*), 3 days (*B*) and 4 h (*C*). Arrows indicate the migration of each of the hybridized DNA fragments.

transforming retroviruses. We used probes obtained from DNA clones of transforming retroviruses capable of inducing a wide range of malignancies and known to contain different *onc* genes. These included avian isolates such as the MC29 virus[24], avian myeloblastosis virus (AMV)[25] and Rous sarcoma virus (RSV)[26], as well as mammalian viruses, including Abelson murine leukaemia virus (A-MuLV)[27], BALB[4] and Moloney[28,29] strains of murine sarcoma virus (MSV), the Snyder–Theilen strain of feline sarcoma virus (ST-FeSV)[30] and simian sarcoma virus (SSV)[31]. Each retroviral *onc* gene probe was prepared from a pBR322 subclone containing only *onc* sequences.

As shown in Fig. 1, the cloned 6.6-kbp *Bam*HI human DNA fragment harbouring the T24 oncogene was readily hybridized with a DNA probe containing 675 bp of v-*bas*, the *onc* gene of BALB-MSV. In the reciprocal experiment, v-*bas* DNA was detected with similar intensity with a probe composed of the T24 oncogene (Fig. 1). Cleavage of the cloned 6.6-kbp *Bam*HI human DNA with the restriction endonuclease *Sac*I is known to generate three fragments of 3.0, 2.7 and 0.85 kbp[32]. Only the 3.0-kbp *Sac*I fragment was detected using v-*bas* as a probe (Fig. 1). These findings firmly established a high degree of relationship between the T24 human bladder carcinoma oncogene and v-*bas*.

No homology was detected between the T24 oncogene and any other *onc* gene tested, with the exception of v-*myc*, the *onc* gene of MC29 virus. However, the degree of relationship between the T24 oncogene and v-*myc* was at least 20–50-fold lower than that detected with v-*bas*, as measured by the relative signal intensity observed (Fig. 1). The possibility that the v-*myc* probe was detecting the subset of T24 oncogene sequences related to v-*bas* was excluded by findings that v-*bas* and v-*myc* showed no homology in identical experimental conditions (data not shown). In fact, it was possible to localize the v-*myc*-related sequences within the 0.85-kbp *Sac*I fragment of the T24 oncogene rather than within the 3.0-kbp *Sac*I fragment containing v-*bas*-related sequences (Fig. 1). Recent studies have localized the transforming region of the T24 oncogene within a 4.6-kbp DNA fragment that contains both the 3.0- and 0.85-kbp *Sac*I fragments[32]. Therefore, these two sets of T24 oncogene sequences, those highly related to v-*bas* and those weakly related to v-*myc*, mapped within the region required for malignant transformation.

c-*bas* (human) is a nontransforming allele of T24 human bladder carcinoma oncogene

As normal human DNA is known to contain sequences related to a variety of retroviruses including v-*bas* and v-*myc*[33], we reasoned that characterization of normal human DNA sequences homologous to each of these transforming genes might shed light on the biological significance of their related sequences. Normal human DNA was digested with *Bam*HI and submitted to Southern blot analysis for detection of sequences related to the T24 oncogene as well as to v-*bas* and v-*myc*. The T24 oncogene and v-*bas* probes both hybridized with a 6.6-kbp *Bam*HI human DNA fragment, suggesting that the normal human v-*bas*-related sequences might represent a normal allele of the T24 oncogene (Fig. 2). In addition, v-*bas* recognized a 3.0-kbp *Bam*HI fragment known to contain another member of the c-*bas* family of genes (S.T. *et al.*, unpublished observations). We also detected hybridization of the T24 oncogene to this 3.0-kbp *Bam*HI human DNA fragment after prolonged exposure (data not shown). In contrast, the v-*myc* probe hybridized with a different subset of human DNA sequences (Fig. 2). These results established that the v-*myc*-related 0.85-kbp *Sac*I fragment of the T24 oncogene did not correspond to the human c-*myc* locus.

To compare the T24 oncogene with normal human sequences related to v-*bas* [designated c-*bas* (human)], we isolated c-*bas* (human) from a library of normal human fetal liver DNA[34]. A recombinant λ Charon 4A phage containing a 19-kbp *Eco*RI insert of human DNA exhibited a 6.4-kbp internal *Bam*HI segment that specifically hybridized with v-*bas*. This 6.4-kbp *Bam*HI fragment was subsequently subcloned in pBR322 and a representative plasmid, designated p344, used for restriction enzyme analysis. As shown in Fig. 3, the restriction map of this 6.4-kbp *Bam*HI fragment of normal human DNA closely

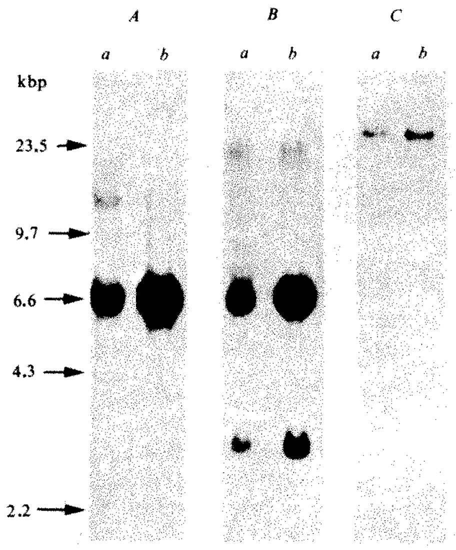

Fig. 2 Detection in human DNA of sequences related to T24 oncogene, v-*bas* and v-*myc*. Twenty microgrammes of high molecular weight DNA isolated from T24 bladder carcinoma (*a*) and M413 normal embryonic human cells (*b*) were digested with 20 U of *Bam*HI for 1 h at 37 °C, electrophoresed in horizontal agarose (0.6% w/v) gels (18 h at 30 V) and blotted to nitrocellulose filters as described previously[42]. Filters were then hybridized in stringent conditions (see Fig. 1 legend) for 44 h to 2×10^7 c.p.m. of the following nick-translated probes: *A*, ^{32}P-labelled 6.6-kbp *Bam*HI T24 oncogene; *B*, ^{32}P-labelled 0.67-kbp *Hin*dIII to *Bam*HI v-*bas*; *C*, ^{32}P-labelled 1.6-kbp *Sac*I to *Bam*HI v-*myc*. Hybridized blots were exposed to Kodak XR-5 film at −70 °C in the presence of intensifier screens for 2 days. Co-electrophoresed DNA fragments of *Hin*dIII-digested λ c1857 DNA served as size standards (labelled in kilobase pairs).

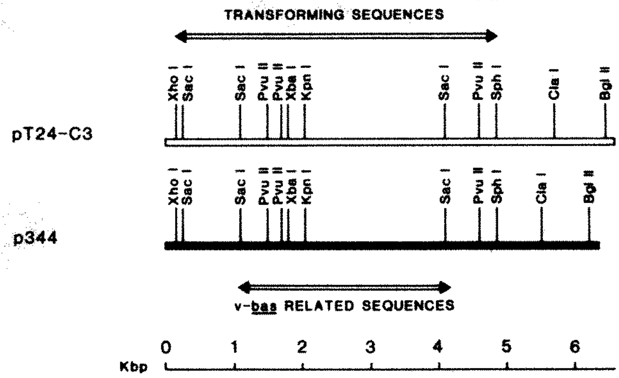

Fig. 3 Comparative restriction maps of the T24 oncogene and c-*bas* (human). The diagram depicts the location of the cleavage sites for *Xho*I, *Sac*I, *Pvu*II, *Xba*I, *Kpn*I, *Sph*I, *Cla*I and *Bgl*II restriction endonucleases within the subcloned *Bam*HI human DNA fragments containing the T24 oncogene (pT24-C3) and c-*bas* (human) (p344). The location of the transforming sequences of the T24 oncogene between the *Xho*I and *Sph*I cleavage sites has been determined elsewhere[32]. The location of the v-*bas*-related sequences within the 3.0-kbp *Sac*I internal fragment of both genes was determined in experiments depicted in Fig. 1.

matched that of the T24 oncogene. In fact, the only detectable difference between the two molecules was a 200-bp deletion that mapped between the *Sph*I and *Cla*I cleavage sites in c-*bas* (human) (Fig. 3). Note that this deletion maps outside the transforming sequences of the T24 oncogene[32], as well as outside the sequences related to v-*bas* (Fig. 3). These results established that c-*bas* (human) is an allele of the T24 bladder carcinoma oncogene.

The T24 oncogene has been shown to transform NIH/3T3 cells efficiently, with a specific activity of ~5×10^4 focus-forming units pmol^{-1} (refs 19, 22, 23). If was of obvious interest to determine whether molecularly cloned c-*bas* (human) sequences exhibited similar biological activity. As much as 1 μg of c-*bas* (human) DNA demonstrated no detectable focus-forming activity whereas in the same experiment, NIH/3T3 cells were readily transformed with as little as 1 ng of the T24 oncogene. The above results, taken together, strongly imply that the acquisition of transforming activity by the T24 oncogene must be the result of subtle genetic alterations.

Organization of v-*bas*-related sequences within the T24 oncogene

The structural relationship between the T24 oncogene and c-*bas* (human) and v-*bas* sequences was studied by heteroduplex analysis. As shown in Fig. 4*a*, c-*bas* (human) and the T24 oncogene were homologous along their entire length, with the exception of a 0.2–0.3 kbp 'loop' located ~1 kbp from one end. These results are consistent with the restriction enzyme maps of these two molecules depicted in Fig. 3. In contrast, heteroduplexes formed between the T24 oncogene and a 0.67-kbp subclone of v-*bas* revealed the presence of a region of homology of about 0.6 kbp in length interrupted by three single-stranded regions of 0.65, 0.14 and 0.27 kbp (Fig. 4*b*). Its v-*bas* homologous sequences were localized within the 3.0-kbp *Sac*I fragment of the T24 oncogene, in agreement with the results obtained by Southern blot analysis (Fig. 3). The coding sequences of v-*bas* are known to reside within the viral RNA strand of the DNA (P. R. Andersen and E. P. Reddy, unpublished observations). By heteroduplex analysis (Fig. 4*b*) it was thus possible to orientate the T24 oncogene as left to right with respect to v-*bas* coding sequences, as shown in Fig. 3.

T24 oncogene products are related to those of the BALB- and Harvey-MSV *onc* genes

Recently, Wigler *et al.* have reported that T24 bladder carcinoma cells exhibit elevated levels of a 1.1-kbp poly(A)-

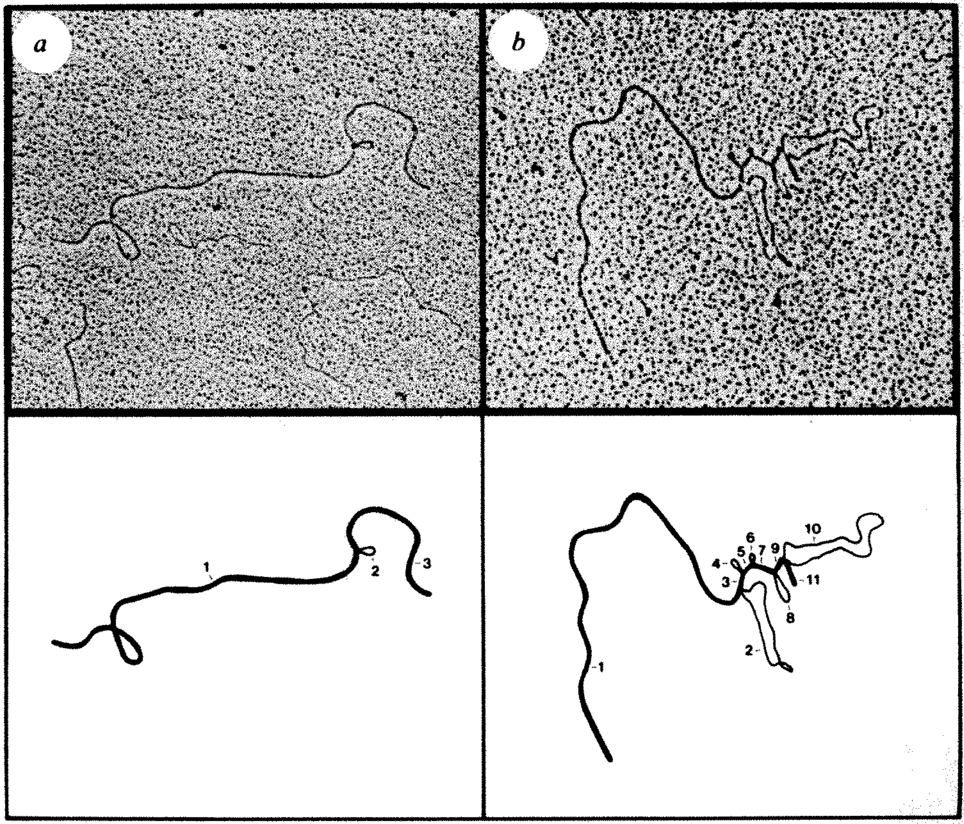

Fig. 4 Heteroduplex analysis of T24 oncogene, c-*bas* (human) and v-*bas*. Heteroduplexes were prepared as described previously[43]. Briefly, DNAs (2 μg ml^{-1}) were denatured with alkali, annealed in the presence of 50% formamide at room temperature for 16 h and spread on to a distilled water hypophase. When pBR322 subclones were used, the supercoiled DNAs were linearized by cleavage with *Sal*I, an enzyme which does not cut any of the inserts. *a*, Heteroduplex formed between T24 oncogene and c-*bas* (human). *Bam*HI inserts purified from pT24-C3 and p344 DNAs, respectively, were used. A representative heteroduplex and an interpretative sketch are represented. Contour lengths (in kbp) of features are as follows: $1=5.2\pm0.25$, $2=0.25\pm0.04$ and $3=1.15\pm0.1$. Fragments 1, 2 and 3 correspond to the 6.6-kbp *Bam*HI DNA fragment containing the T24 oncogene. Fragments 1 and 3 correspond to the 6.4-kbp *Bam*HI DNA fragment containing c-*bas* (human). *b*, Heteroduplex analysis of T24 oncogene and v-*bas*. A representative heteroduplex between pT24-C3 and pHB1 DNA, a plasmid that contains the 0.67-kbp *Hin*dIII to *Bam*HI fragment of v-*bas*, and an interpretative sketch are represented. Contour lengths (kbp) of relevant features are as follows: $1=3.9\pm0.2$, $2=1.8\pm0.2$, $3=0.10\pm0.02$, $4=0.27\pm0.03$, $5=0.10\pm0.02$, $6=0.14\pm0.02$, $7=0.2\pm0.02$, $8=0.65\pm0.05$, $9=0.25\pm0.03$, $10=3.0\pm0.2$, $11=0.25\pm0.03$. Fragments 1 and 11 correspond to pBR322 sequences. Fragments 3, 5, 7 and 9 correspond to v-*bas* sequences. Fragments 2, 4, 6, 8 and 10 correspond to the 6.6-kbp *Bam*HI DNA fragment containing the T24 oncogene.

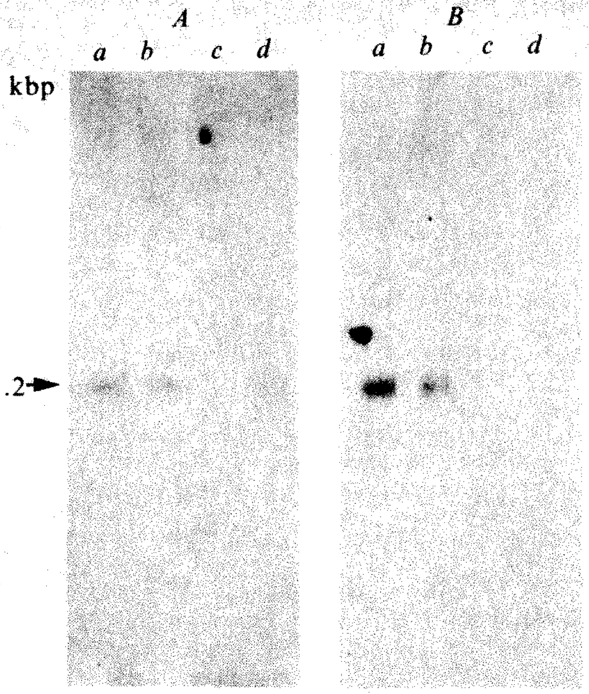

Fig. 5 T24 oncogene and v-*bas*-related transcripts in human cell lines. *a*, *b*, Poly(A)-containing RNA, isolated from T24 bladder carcinoma cells (two independent preparations); *c*, M413 normal embryo cells; *d*, HT-1080 fibrosarcoma cells were obtained as previously described[44,45]. RNA samples (5 μg) were denatured in 13 mM methylmercury hydroxide and size fractionated in horizontal agarose (1% w/v) gels containing 5 mM methyl mercury[46]. Electrophoresed gels were blotted to nitrocellulose filters which were subsequently hybridized with 10^7 c.p.m. of the following nick-translated probes: *A*, ^{32}P-labelled 6.6-kbp *Bam*HI T24 oncogene; *B*, ^{32}P-labelled 0.67-kbp *Hin*dIII to *Bam*HI v-*bas*. Hybridization was performed in 50% formamide, 5 × SSC at 37 °C for 44 h. Hybridized blots were exposed to Kodak XR-5 films at −70 °C in the presence of intensifier screens for 4 days. The arrow indicates the size of the detected transcript as deduced from its relative migration with respect to ribosomal RNA size standards.

containing RNA that specifically hybridized with the T24 oncogene[20]. This transcript was also detected in normal cells, although at much lower levels. As shown in Fig. 5*A*, similar results were obtained in our laboratory. To establish whether the v-*bas*-related sequences of the T24 oncogene were transcribed, poly(A)-containing RNA of T24 cells was submitted to Northern blot analysis. As shown in Fig. 5*B*, a 1.2-kbp RNA molecule hybridized with both the T24 oncogene and v-*bas* probes. These results indicated that v-*bas*-related sequences are an integral part of the T24 oncogene transcript.

The transforming gene product of v-*bas* has been identified as a polypeptide with an apparent molecular weight of 21,000, designated p21^{bas} (ref. 4). An antigenically related protein, p21^{ras}, has been identified as the gene product of Harvey-MSV[35], another murine sarcoma virus whose *onc* gene is closely related to that of BALB-MSV[4]. Antisera obtained from BALB- and Harvey-MSV tumour-bearing rats were used to search for the putative T24 oncogene translational product in a variety of human tumour cells including parental T24 bladder carcinoma cells. As shown in Fig. 6, low levels of a protein migrating with an apparent molecular weight of 21,000 were detected in M413 normal human embryo fibroblasts[36] as well as in HT-1080 human fibrosarcoma cells[37]. Similar results were observed with a variety of human tumour cell lines established from tumours other than bladder carcinomas (data not shown). This p21 protein was also detected in T24 cells but at somewhat elevated levels. In addition, T24 cells contained an antigenically related 23,000 molecular weight protein which was not detected in any of the other human cells analysed (Fig. 6).

To investigate further whether this protein was coded for by the T24 oncogene, we analysed NIH/3T3 cells transformed by this gene (Fig. 6*D*). Such transformants expressed levels of the p23 protein comparable with those detected in T24 cells. In addition, T24 oncogene-transformed NIH/3T3 cells expressed high levels of a p21 protein that co-migrated with the gene product of BALB-MSV (Fig. 6). Whether this protein represents a post-translationally modified human p23 molecule or the endogenous mouse p21 protein, remains to be determined. In either case, our findings support the concept that the T24 oncogene encodes a protein immunologically related to the transforming gene products of BALB- and Harvey-MSV.

Implications

Recent intensive investigation of acute transforming retroviruses has led to considerable knowledge concerning their genomes and translational products, as well as their interactions with the host[1]. Thus, our demonstration that the T24 oncogene represents an activated human cellular analogue of a retroviral *onc* gene should make it possible to apply this knowledge to understanding the mechanisms by which the T24 oncogene induces transformation. By use of high titred antisera directed against the BALB and Harvey MSV-coded p21 proteins[4,35], we were able to detect an antigenically related p23 protein specifically expressed in T24 cells. It should be possible to

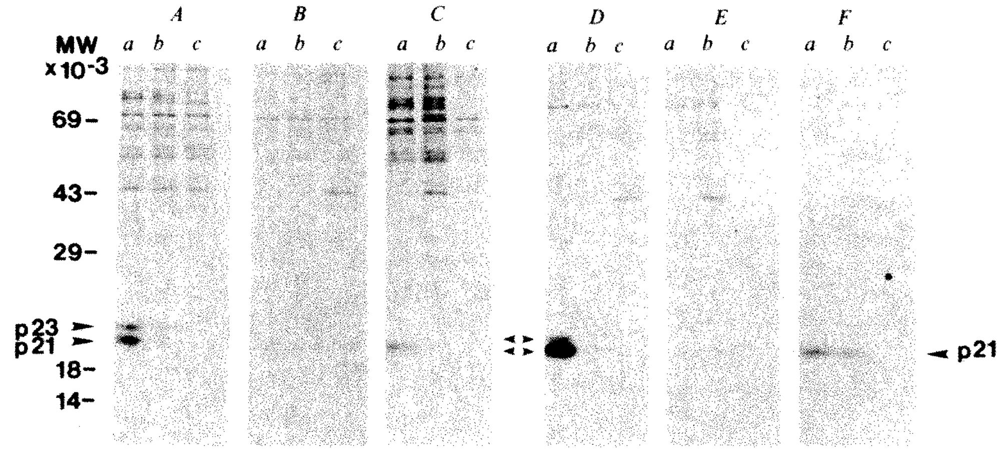

Fig. 6 Detection of proteins antigenically related to the *onc* gene products of BALB- and Harvey-MSV in human tumour cell lines and in NIH/3T3 cells transformed by the T24 oncogene. Exponentially growing cells (~2 × 10^6 cells per immunoprecipitation reaction) including: *A*, T24 human bladder carcinoma cells; *B*, M413 normal human embryonic fibroblasts; *C*, HT-1080 human fibrosarcoma cells; *D*, 44-91 NIH/3T3 cells transformed by the T24 oncogene; *E*, NIH/3T3 mouse cells; *F*, NIH/3T3 cells nonproductively transformed by BALB-MSV, were labelled with ^{35}S-methionine as previously described[47]. Radiolabelled cell extracts were incubated for 1 h at 4 °C with 0.005 ml of sera obtained from: *a*, Harvey-MSV-induced tumour-bearing rats; *b*, BALB-MSV-induced tumour-bearing rats; *c*, uninfected normal rats. Immunoprecipitates, collected with the aid of *Staphylococcus aureus* protein A bound to Sepharose 4B beads, were disrupted in the presence of 1% SDS and 2% 2-mercaptoethanol and analysed by electrophoresis in 8–16% linear gradient SDS-polyacrylamide gels. Electrophoresed gels were dried, fluorographed[48] and exposed to Kodak XR-5 films for 4 days at −70 °C. Molecular weight (MW) markers co-electrophoresed with the above samples included bovine serum albumin (69,000), ovalbumin, indicated by arrows.

establish whether this protein is present in other human bladder carcinoma cells or in other naturally occurring tumours. Such an approach may help in determining whether the T24 oncogene has an aetiological role in human neoplasia.

Detection of dominant human transforming genes by DNA-mediated gene transfer techniques has generally required the use of the NIH/3T3 cell line as the recipient assay cell[12-16,18,19]. As NIH/3T3 is a continuous, heteroploid cell line[38], it is possible that genes which transform this cell line might be unable to transform normal cells. It is known that both v-*bas* and v-*ras* are capable of inducing a variety of malignancies in animals[39-41]. Thus, it seems likely that when the human cellular homologue of these *onc* genes is activated, as in the case of the T24 oncogene, this gene would possess the capacity to transform normal cells as well.

The number of different genes that are activated as dominant transforming genes in human tumours is not known[12-19]. DNAs isolated from carcinomas of the colon and pancreas as well as from a fibrosarcoma and a rhabdomyosarcoma have been shown to transform NIH/3T3 cells in transfection assays (ref. 19 and M.B. *et al.*, unpublished). Although none of these putative human oncogenes has been found to correspond to the human homologues of retroviral *onc* genes used in the present studies, our findings that c-*bas* (human) is a nontransforming allele of the T24 oncogene suggest that additional relationships between human oncogenes and retroviral *onc* sequences may be uncovered.

It has been well established that the cellular sequences transduced by retroviruses require viral genetic information in order to induce malignancy. The present studies demonstrate that at least one of these cellular sequences, c-*bas* (human), can be activated by a mechanism not requiring recombination with retroviral sequences. Detailed restriction enzyme analysis of this gene and its transforming allele, the T24 oncogene, has not revealed detectable differences. Thus, we must conclude that subtle genetic changes have caused the activation of this gene. Comparative sequence analysis of the T24 oncogene and c-*bas* (human) will ultimately define, not only the nature, but the number of genetic changes that led to the acquisition of transforming activity by c-*bas* (human) in T24 bladder carcinoma cells.

We thank Anne V. Lauver, Carole K. Lengyel and Linda K. Long for technical assistance, Holly Fuhrer for photographic work, and the following investigators for providing *onc* gene probes: T. Papas (v-*myc*), M. Baluda (v-*myb*) and G. Cooper (v-*src*).

The surface antigen of hepatitis B virus (HBsAg) has been synthesized in the yeast Saccharomyces cerevisiae *by using an expression vector that employs the 5′-flanking region of yeast alcohol dehydrogenase I as a promoter to transcribe surface antigen coding sequences. The protein synthesized in yeast is assembled into particles having properties similar to the 22-nm particles secreted by human cells.*

HEPATITIS B virus[1-3] is a 42-nm particle (the Dane particle) consisting of a core containing the viral genome (~3,200 base pairs (bp) of partially single-stranded DNA[4]) bound to the core protein and its own DNA polymerase[5-9]; the virus core is surrounded by a phospholipid-containing envelope carrying the major surface antigenic determinants (HBsAg). These seem to

0028-0836/82/290347—04$01.00

reside mainly in a single protein, which occurs in both a glycosylated and non-glycosylated form (molecular weight (M_r) 27,000–29,000 and 23,000–25,000, respectively, as measured on SDS gels[10,11]). Infection with hepatitis B virus (HBV) leads not only to the production of Dane particles but also to a dramatic overproduction of 22-nm large particles and filaments (the HBsAg particle) that contain the elements of the surface envelope. These HBsAg particles are about 1,000-fold more immunogenic than the unassembled HBsAg protein[12]. Because of its narrow host range (humans and chimpanzees), and as it cannot be propagated in tissue culture, investigation of the structure and mechanism of infection of HBV has been severely restricted. The advent of molecular cloning has allowed the mplete virus genome to be cloned and sequenced[5–7,13–15], and the coding regions for the different antigens have been identified[5–7], raising the possibility of expressing HBV genes in alternative host systems. However, in previous attempts, high level production of HBsAg-related immunogenic material was not achieved in bacteria even in systems using powerful bacterial promoters[14,16,17]. We therefore examined yeast as an alternative host system; this organism has complex membrane systems and the ability to secrete and glycosylate proteins by processes resembling those observed in higher cells[18]. Recently, yeast has also been developed to give a system which allows the introduction, maintenance and expression of foreign genes[19–21]. Here we report the construction of an autonomously replicating plasmid containing HBsAg-coding sequences linked to the yeast alcohol dehydrogenase I promoter. Yeast transformed with these vectors synthesize and accumulate particulate material that specifically reacts with antibodies against HBsAg.

Construction of plasmids and expression of HBsAg in yeast

The HBsAg-coding sequence used in these studies was isolated on a 835-bp *Taq*I–*Hpa*I fragment[13,16]. This fragment contains 26 bp preceding the AUG which encodes the N-terminal methionine of mature HBsAg. It lacks the DNA sequence of 489 or 522 bp that encodes a presumptive precursor which can be deduced from the viral genomic sequence[7]. The HBsAg gene fragment was joined to the yeast alcohol dehydrogenase (ADHI) promoter as described in Fig. 1 legend. The plasmid

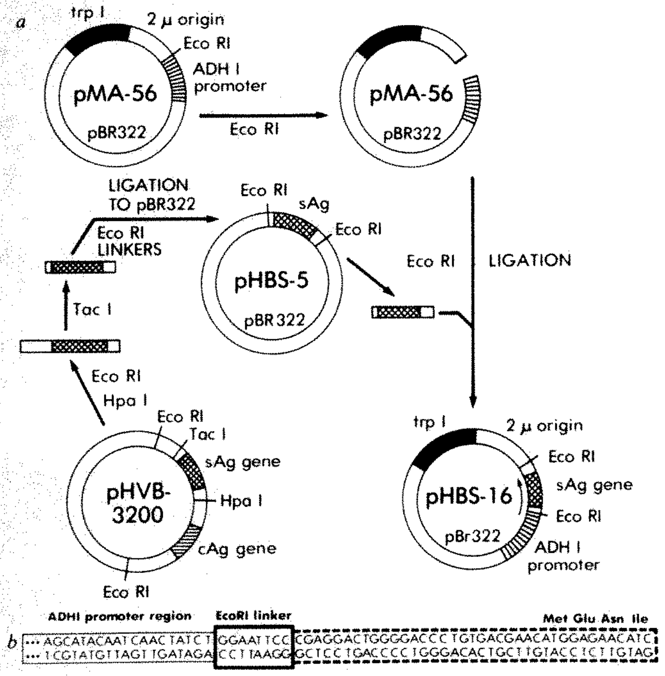

Fig. 1 *a*, Construction of plasmids for the expression of hepatitis B surface antigen in yeast. pMA-56 was constructed from YRp7 (ref. 27) by (1) removing one of its *Eco*RI sites (digestion with *Eco*RI, fill-in by DNA polymerase I Klenow fragment and blunt-end ligation); (2) replacing the yeast *ars*-1 replication origin by a *Pst*I–*Eco*RI fragment containing the replication origin of yeast 2 μ plasmid; and (3) replacing the smallest *Eco*RI–*Bam*HI of the resulting plasmids by a 1,500-bp *Eco*RI–*Bam*HI fragment containing the yeast ADHI promoter[21]. Sixty microgrammes of pHBV-3200[13] were digested with *Eco*RI and *Hpa*I, and the 1,000-bp fragment containing the surface antigen gene was isolated and digested with *Tac*I; 10 μg of the resulting 800-bp fragment were ligated to *Eco*RI linkers and cloned in the *Eco*RI site of pBR322 (pHBS-5). The *Eco*RI fragment containing the HBsAg was isolated from pHBS-5 by preparative gel electrophoresis after digestion with *Eco*RI, and ligated to pMA-56 (previously linearized by *Eco*RI and treated with bacterial alkaline phosphatase). After transformation of *E. coli* cells (RR1) and isolation of DNA by a small scale procedure[28], recombinant plasmids were analysed by cleavage with restriction endonucleases. Plasmids in which the HBsAg gene was in line with the ADHI promoter (pHBS-16), and those with these regions in the opposite orientation (pHBS-20) were amplified and used to transform strain XV610-8C *a ade2 ade6 leu2 lys1 trp1 can1* as described elsewhere[19]. *b*, DNA sequence of the ADHI–HBsAg gene junction present in pHBS-16. The sequence was obtained by the method of Maxam and Gilbert[29].

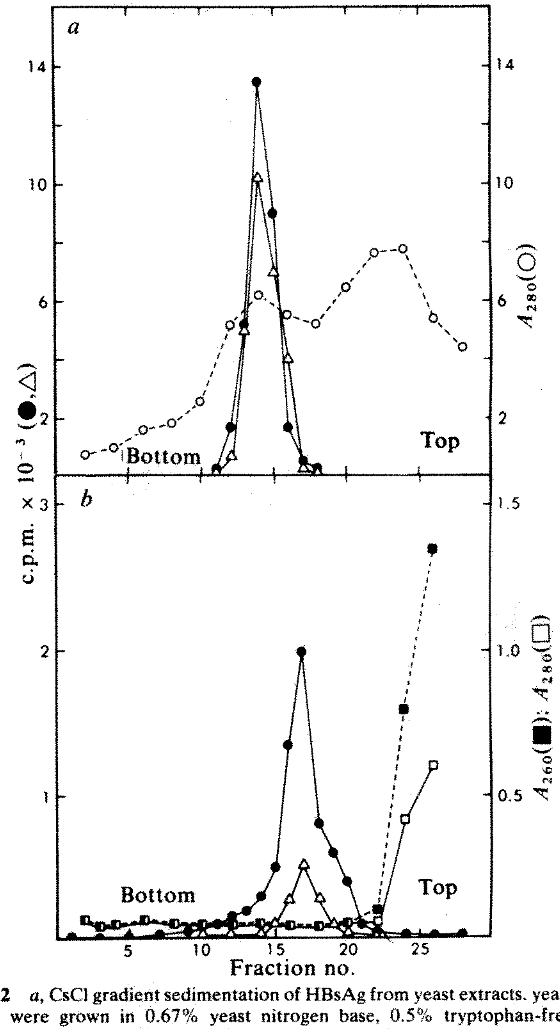

Fig. 2 *a*, CsCl gradient sedimentation of HBsAg from yeast extracts. yeast cells were grown in 0.67% yeast nitrogen base, 0.5% tryptophan-free casamino acids and 2% glucose. Cells from a 100 ml culture were pelleted, washed in 100 ml of buffer (10 mM phosphate *p*H 7.5, 0.1% Triton X-100), suspended in one volume of packed cells of the same buffer and broken by vortexing with glass beads (0.45–0.50 mm diameter). After centrifugation, a 0.5-ml aliquot of the extract was layered on to a 12 ml discontinuous 1.1–1.4 g cm^{-3} CsCl gradient in 10 mM phosphate buffer (*p*H 7.4) and run at 30,000 r.p.m. at 5 °C for 24 h in a beckman SW41 rotor. Fractions (0.5 ml) were collected from the bottom of the tube. The HBsAg activity was measured using the radioimmunoassay AUSRIA II (Abbott). The HBsAg used as standard was isolated from supernatants of PLC/PRF/5 cells[25,26]. *b*; Sucrose gradient sedimentation of HBsAg produced in yeast cells. Active fractions from the above CsCl gradient were pooled and dialysed against 10 mM phosphate buffer *p*H 7.5. A 0.5-ml aliquot was layered on to a 12 ml 5–30% sucrose gradient in 10 mM phosphate buffer containing 0.15 M NaCl and run at 33,000 r.p.m. at 5 °C for 6 h in a Beckman SW41 rotor. Fractions (0.5 ml) were collected and aliquots assayed as for *a*. A 0.5-ml sample of PCL/PRF/5 cell supernatant was used as standards in the same way. ●, Yeast; △, Alexander cells for *a* and *b*.

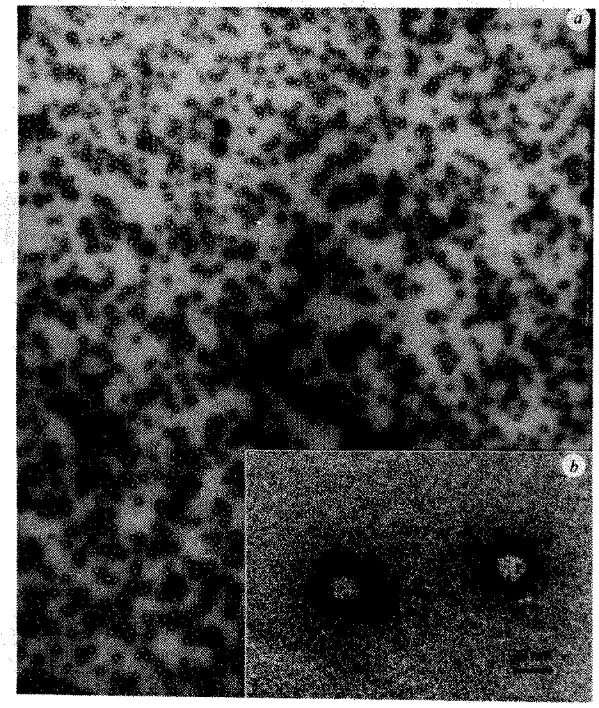

Fig. 3 Electron micrographs of HBsAg particles produced by yeast cells. *a*, Particles were purified by adsorption to a column of goat anti-HBsAg specific antibody covalently bound to Sepharose, eluted with 3 M potassium thiocyanate and visualized by negative staining with 2% phosphotungstic acid. ×25,000. *b*, Higher magnification of particles purified by a combination of CsCl and sucrose gradient sedimentation and visualized after negative staining with 2% uranyl acetate. ×250,000.

contains *Escherichia coli* vector pBR322, a replication origin derived from the yeast 2 μ plasmid, the *trp*1 gene for selection in yeast cells, and the ADHI promoter inserted into the *tet*^{r} region of pBR322. The efficacy of the ADHI promoter for expression of a linked coding sequence has recently been demonstrated by the production of interferon in this system[22]. Yeast cells (XV610-8C) were transformed by recombinant plasmids in which the HBsAg gene was placed either in the same 5′–3′ orientation as the ADHI promoter (pHBS-16) or in the opposite orientation (pHBS-20). Cell extracts from mid-log phase cultures of these strains were assayed for HBsAg by radioimmunoassay (AUSRIA II; Abbott). A substantial level of HBsAg was detected only in the cells transformed with pHBS-16; no surface antigen was observed in cells transformed with the plasmid in which the viral gene is incorrectly oriented. The amount of surface antigen protein made per 200 ml of yeast culture was ~2–5 μg, calculated from the radioimmunoassay data.

Nature of viral antigen produced in yeast

The predominant form of HBsAg produced by human cells is the so-called 22-nm particle. Its biophysical properties are well documented[23,24] and its immunological potency exceeds that of the pure protein[12]. To examine the form in which surface antigen is present in yeast, we subjected extracts to equilibrium sedimentation through a discontinuous CsCl gradient. A control tube containing HBsAg from a human hepatoma cell line (Alexander or PLC/PRF/5 cells[25,26]) was treated identically to provide a buoyant density marker. Surprisingly, HBsAg synthesized by yeast was found to band at the same density as that from the PLC/PRF/5 cell, that is, ~1.2 g cm^{-3} (Fig. 2*a*). Peak fractions of the CsCl gradient were analysed further by velocity sedimentation in sucrose gradients. Again the peak of HBsAg produced by yeast coincided exactly with HBsAg from human cells (Fig. 2*b*), which sediments at ~55S[24].

From the sedimentation data, it is apparent that HBsAg is synthesized in yeast in the form of particles or aggregates. The nature of these particles was further characterized by electron microscopy. HBsAg synthesized in yeast was purified again by a combination of sedimentation in CsCl and sucrose gradients. The immunoreactive material was adsorbed onto carbon film grids and negatively stained with uranyl acetate by Drs P. Bull and J. Garrido (Catholic University, Santiago, Chile). Alternatively, yeast HBsAg was purified by affinity chromatography and negatively stained with phosphotungstic acid by Drs G. Wampler, W. Ziegler, W. Miller and W. McAleer (Merck Sharp and Dohme Research Laboratories). When examined under the electron microscope, the yeast HBsAg preparation was found to contain particles (Fig. 3*a*,*b*) which appeared very similar to those secreted by Alexander cells. The particles purified and stained using the first method are ~20 nm in diameter. A more extensive analysis showed that the size of the purified particles eluting with 3 M ammonium thiocyanate from an affinity column is variable, the medium size being ~17 nm (W. Miller and W. McAleer, personal communication).

Preliminary tests have shown that these particles are antigenic, inducing antibodies in animal species (G. Buynak and W. McAleer, personal communication). It has been demonstrated previously[12] that integration of the HBsAg protein into a phospholipid structure to form the 22-nm particle dramatically increases its immunogenic properties. Thus the immunogenicity of the material synthesized in yeast is further evidence that its structure resembles that of the 22-nm particle.

The chemical composition of HBsAg molecules synthesized in yeast was determined by immunoprecipitation of ^{35}S-proteins labelled *in vivo* in a yeast strain transformed by the ADHI–HBsAg recombinant plasmid. SDS-gel electrophoresis of the anti-HBsAg immunoreactive material (Fig. 4) revealed a single band of apparent M_r 23,000, corresponding in size to the unglycosylated HBsAg component of PLC/PRF/5 cells[11]. No higher molecular weight bands could be detected, indicating that most of the molecules were not glycosylated in these conditions.

Conclusions

Expression of hepatitis B surface antigen coding sequences in yeast leads to the production of particles immunoreactive with anti-HBsAg antibodies. These particles are similar to those

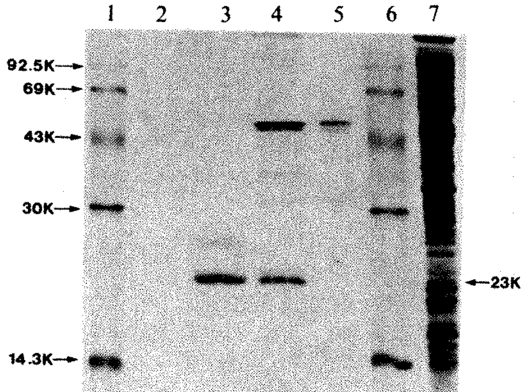

Fig. 4 Autoradiography of SDS-polyacrylamide gel of HBsAg proteins produced by yeast and PLC/PRF/5 cells. Yeast cultures and PLC/PRF/5 cells were grown in the presence of ^{35}S-methionine and ^{35}S-cysteine. Yeast cells were collected, broken by vortexing with glass beads and the resulting extracts clarified by centrifugation. Labelled HBsAg particles from PLC/PRF/5 cell supernants were concentrated by ultracentrifugation and used as a control. Proteins from yeast and PLC/PRF/5 cells were immunoprecipitated using the SAC technique[30]. Samples were run on 12.5% acrylamide gels according to Laemmli[31], subjected to fluorography[32], dried and exposed to X-ray film. Lanes 1 and 6, ^{14}C-methylated proteins as molecular weight standards: phosphorylase (92,500, 92.5K), bovine serum albumin (69K), ovalbumin (46K), carbonic anhydrase (30K) and lysozyme (14.3K); lane 2, PLC/PRF/5 cell supernatants plus normal human serum; lane 3, PLC/PRF/5 cell supernatant plus human anti-HBsAg serum; lane 4, yeast extracts from strain XV610-8C with pHBS-16 plus human anti-HBsAg serum; lane 5, yeast extracts from strain XV610-8C with pHBS-16 plus normal human serum; lane 7 aliquot of total yeast ^{35}S-labelled proteins. Numbers at the left refer to protein markers as above. The number at the right indicates the 23,000-M_r protein immunoprecipitated from yeast and PLC/PRF/5 cells.

made by human carrier patients or by a hepatoma cell line; they have identical sedimentation rates and buoyant density, suggesting a similar size and ratio of protein to lipid composition for yeast and for human particles. Electron microscopic observation established that the yeast particles are more variable in size and have a smaller mean diameter than the human particles. Furthermore, unlike the HBsAg from human cells, the yeast particle does not contain significant quantities of a higher molecular weight glycoprotein, indicating that glycosylation is required neither for the formation of the particulate structures nor for immunogenicity.

The construction we have used in the HBsAg-expressing plasmid eliminates that part of the gene encoding the leader peptide of putative pre-HBsAg[7]. Therefore, formation of particles in yeast implies that the polypeptide sequence of the surface antigen molecule contains the requisite instructions for assembly of apparently normal particles within the cytoplasmic milieu of the yeast cell. The leader region and other possible precursors formed by its translation are not required for the formation of this structure. Furthermore, no other hepatitis gene products or liver-specific cell products are necessary to form the particulate structure. It seems likely, therefore, that such particles can be formed in many other heterologous cell systems, perhaps even in bacteria. It remains to be determined where within the yeast cell the 22-nm particle is assembled, and what biochemical processes accompany it. An immediate advantage of the yeast system is that the physiological and genetic requirements for particle assembly may be systematically explored, making use of yeast mutants conditionally defective for the secretory pathway[18] and for other aspects of cellular metabolism.

The similarity in structure of the yeast particle to bona fide 22-nm particles and the high immunogenicity in animals emphasize the possible value of the HBsAg particle as a vaccine. The yeast HBsAg particles can in principle be produced in large quantities for this purpose. Further, the complete absence of intact HBV and/or human proteins in such preparations eliminates the possibility of secondary infections or autoimmunity problems as a result of the vaccine.

Finally, our findings illustrate the versatility of recombinant DNA methodology for the production of complex structures. Previously, recombinant DNA techniques as applied to microorganisms have only been used to produce simple proteins like insulin, growth hormone, interferon and enzymes. Our experiments suggest that more complicated structures can be formed in alternative hosts like yeast provided the genes for the requisite organizing proteins are introduced and efficiently expressed. This offers an effective approach for the analysis of organelles in higher organisms.

We thank P. Bull, J. Garrido and B. Wolanski, R. Ziegler, W. Miller and W. McAleer for the electron microscopic analysis; L. Rall for the preparation of ^{35}S-labelled HBsAg particles from PLC/PRF/5 cells; and M. Worthington and S. Bektech for the construction of pMA-56. This research was funded by grants from Merck Sharp and Dohme Research Laboratories. G.A. was supported by a grant from the Max Kade Foundation.

Note added in proof: Since the submission of this paper, particles containing a different HBV protein, the virus core antigen, have been reported in *E. coli* carrying a recombinant plasmid[33].

Evidence for an oblique magnetic solar rotator

D. O. Gough

Institute of Astronomy, Madingley Road, Cambridge CB3 0HA, UK

The observation by Claverie *et al*[1]. of fine structure in the peaks in the power spectrum of low-degree 5-min solar oscillations has been interpreted as being a result of rotational splitting. Claverie *et al*.[1] claim that their measurements imply that an appropriately weighted average $\bar{\Omega}$ of the interior angular velocity $\Omega(r)$ of the Sun is about twice the value of Ω at the surface. At first sight their claim looks doubtful, because all $2l+1$ components of the set of modes of degree l appear in the spectrum, whereas only $l+1$ of them should be detectable. However, Isaak[2] has recently speculated that the additional components are produced by an intense rotating magnetic core, such as had been postulated by Dicke[3],[4] to account for the 12.2-day periodic component in the Princeton oblateness data[5-9]. Isaak[2] pointed out that the mean period $2\pi/\bar{\Omega} \simeq 15$ days of the solar interior that was inferred from the Birmingham data[1] is consistent with a central core rotating with the 12.2-day period and an outer envelope rotating with the photosphere. Moreover, his rough estimate of a few megagauss for the r.m.s. magnetic field that is required to support his conjecture is within about a factor 10 of that required by Dicke[3]. Thence he concluded that the Birmingham data[1] provide the first clear empirical evidence for an intense internal solar magnetic field. Here I examine this evidence in more detail, and show that the conclusion is premature. If the magnetic core does exist, the 5-min oscillations provide no clear evidence that it is rotating rapidly. Furthermore, unless one accepts a contrived magnetic-field configuration, an explanation for the $2l+1$ components of the multiplets is still lacking.

With respect to spherical polar coordinates (r, θ, ϕ) about any axis, the linear eigenfunctions of oscillation of a spherically symmetrical star of radius R are separable in radial and angular coordinates. For example, the radial component δr of the dis-

0028-0836/82/290350—05$01.00

placement eigenfunction can be written:

$$\delta r(\mathbf{r}, t) = Re[\xi(r) P_l^m(\cos\theta)\, e^{im\phi - i\omega t}], \qquad |m| \leq l \tag{1}$$

where P_l^m is the associated Legendre function. For any given value of the degree l, there is a discrete set of modes. Each mode in the set is labelled by an integer n, called the order of the mode, which is equal to the number of zeros of $\xi(r)$ for $0<r<R$, $(0\leq r<R$ when $l=0)$, except possibly when n is small. The frequencies of the p modes, which are the subject of this discussion, increase with n.

The degree l measures the total horizontal wavenumber. The angular order m measures its azimuthal component about the coordinate axis. Unlike m, l is independent of the orientation of the coordinate axis; indeed, any spherical harmonic of degree l transforms under coordinate rotations into a linear combination of the harmonics of that degree. Evidently the eigenfrequencies of a spherically symmetrical star cannot depend on the orientation of the axis. Therefore the frequencies ω and eigenfunctions $\xi(r)$ are independent of m.

Unless $m = 0$, the representation (1) is of a wave propagating about the axis with angular phase speed $m^{-1}\omega$. Since ξ and ω are independent of m, it is possible to combine two such waves with equal and opposite m to form a standing wave.

By comparing with theory the power spectra of the observed low-degree oscillations[1,10–17] it has been possible to identify the modes. In particular, the modes isolated by Claverie *et al.*[1] lie in the range: $0\leq l\leq 2$, $16\leq n\leq 27$. For this discussion, the values of n are sufficiently large for asymptotic theory[18,19] to be adequate. Furthermore, it is sufficient to assume the oscillations to be adiabatic, with ξ and ω real.

Any deviation of the equilibrium state of the star from spherical symmetry is liable to destroy the simple structure of the eigenfunctions exhibited in equation (1). In the Sun it is known that symmetry is broken by rotation. It is also broken by magnetic fields. The effect on the eigenfrequencies is to split the degeneracy with respect to m. The question under investigation here is whether the splitting that has been observed in the Sun compels us to conclude that strong magnetic fields are present.

Let us consider first the effect on the modes of rotation alone. Viewed from a coordinate frame rotating with angular velocity Ω_0 about the rotation axis of the Sun, and granted that the solar angular velocity Ω measured in an inertial frame is small, the principal modifications to the motion that arise are due to Coriolis forces and advection of the wave pattern by the relative angular velocity $\Omega-\Omega_0$. For high-order p modes the Coriolis effect is small; by substituting the appropriate asymptotic form[19] for the eigenfunction into equations (7), (8) of ref. 20 it can be shown that advection augments the frequency by approximately

$$\Delta\omega = mI^{-1}\int_0^R c^{-1}(\Omega-\Omega_0)\,\mathrm{d}r \equiv m(\bar{\Omega}-\Omega_0) \tag{2}$$

where

$$I=\int_0^R c^{-1}\,\mathrm{d}r \tag{3}$$

and c is the sound speed in the equilibrium state. Here it has been assumed that Ω is a function of r alone. Thus, with respect to an inertial spherical polar coordinate system about the rotation axis, the total frequency is

$$\omega = \omega_0 + m\Omega_0 + \Delta\omega = \omega_0 + m\bar{\Omega} \tag{4}$$

where ω_0 is the frequency of the corresponding mode of an equivalent nonrotating star[17]. Notice that $\bar{\Omega}$ is independent of m. Therefore the frequencies of the modes of given degree l and order n are uniformly spaced, with separation $\bar{\Omega}$. In particular, it follows from equation (4) that any standing wave pattern formed by a superposition of rotationally split modes precesses without dispersion about the rotation axis of the Sun with angular velocity $\bar{\Omega}$. In the frame of the standing wave, frequency is independent of m.

This behaviour is modified when one acknowledges that Ω is really a function of both r and θ. The splitting is no longer precisely uniform, because modes with different values of m sample the latitudinal variation of Ω differently. For example, if the angular velocity of the Sun is approximated by $\Omega(r)$ $(1-\alpha\cos^2\theta)$ with α constant and positive, the high-order p-mode eigenfrequencies can be shown to be

$$\begin{aligned}\omega &= \omega_0 + m\left\{1-\frac{\alpha}{2}(2l+1)\frac{(l-|m|)!}{(l+|m|)!}\int_{-1}^{1}[\mu P_l^m\mu)]^2 d\mu\right\}\bar{\Omega}\\ &\equiv \omega_0 + m\beta\bar{\Omega}\end{aligned} \tag{5}$$

Thus as $|m|$ increases at fixed l the splitting increases, because the eigenfunctions become more concentrated towards the more rapidly rotating equator. The concentration is accentuated as l increases, and the mean spacing, which is $[1-(2l+3)^{-1}\alpha]\bar{\Omega}$, approaches $\bar{\Omega}$ as $l\rightarrow\infty$. However, when l is small the variation is also small: taking $\alpha\simeq 0.2$ yields a splitting between quadrupole modes with $m=1$ and $m=2$ only 6% greater than the splitting between those with $m=0$ and $m=1$, and roughly equal to the splitting of the dipole modes.

According to Claverie *et al.*[1], the major peaks in the power spectrum of their data are either single, or split into approximately uniformly spaced triplets or quintuplets. The mean spacing of the triplets is ~0.67 μHz synodic, and that of the quintuplets, which are less clearly resolved, is ~25% greater. The overall mean spacing is 0.75 μHz.

The signal obtained by Claverie *et al.* is a measure of the time-varying shift in a solar spectrum line. The light is integrated over the entire solar disk[20]. Therefore, if the solar rotation axis were perpendicular to the line of sight, pure modes for which $l+m$ is odd could not contribute to the signal. This follows directly from the symmetry properties of tesseral harmonics. Thus, of all the modes of degree l, no more than $l+1$ of the $2l+1$ possible values of m should be detected. At the time of the observations the Sun's axis was tilted from the plane of the sky by about 6°. As pointed out by Isaak[2], this is insufficient to have produced a detectable signal from the otherwise invisible modes, unless of course, modes with odd $l+m$ systematically have 10 times the amplitude of the others.

If one were to assume with Claverie *et al.*[1] that the fine structure in the Birmingham power spectrum is rotational splitting, the most naive interpretation would be that the triplets correspond to $l=2$ and the quintuplets to $l=4$. Then the mean splitting between adjacent components of the multiplets would be $2\beta\bar{\Omega}\simeq 2\bar{\Omega}$, implying a mean interior rotation rate of ~0.38 μHz. This is similar to the rotation rate of the photosphere, which is 0.42 μHz synodic at the equator.

This interpretation faces several difficulties, such as the problem of explaining why doublets presumed to be associated with dipole modes (to which the observations are most sensitive[17]) are not prominent in the spectrum. But most important is that it is contradicted by the mode identification made previously[1,10,13–15], which depends on the qualitative structure of the patten apparent in the frequencies of the modes[13–18,21]. That pattern, which repeats as n increases, consists of approximately uniformly spaced groups of modes, of alternately odd and even degree. It is a basic signature of the eigenvalues of the wave equation that describes asymptotically high-order modes in any spherically symmetrical system. Though the absolute values of the theoretical eigenfrequencies are dependent on the solar model, the pattern in which they are distributed is a basic geometrical property. It is a consequence of the fact that the Sun is essentially a sphere (and not, for example,

Table 1 Frequencies of high-order dipole p modes in a rotating magnetic star

m'	$m=-1$	$m=0$	$m=+1$
0	$\omega_0+\delta_0\omega-\beta\bar{\Omega}$	$\omega_0+\delta_0\omega$	$\omega_0+\delta_0\omega+\beta\bar{\Omega}$
1	$\omega_0+\delta_1\omega-\beta\bar{\Omega}$	$\omega_0+\delta_1\omega$	$\omega_0+\delta_1\omega+\beta\bar{\Omega}$

a cube). Therefore, whilst one might suspect that n has been incorrectly assigned, the identification of l is robust: the triplets found by Claverie *et al.* have $l=1$, and the quintuplets $l=2$. So why is it that there are more components in the observed spectrum than should be expected?

Of course, all the components would be detectable if the solar interior were rotating about an axis that is inclined to that of the photosphere. In that case, because it would be quite unlikely that the axis of mean rotation would precess about the photospheric axis with the same angular velocity as the Earth's orbital rotation about the Sun, the relative heights of the rotationally split components in the power spectrum would be modulated on a time scale of a year. This could be checked by observation.

The presence of the central dipole component strongly suggests to Isaak[2] the existence of a perturbation which is inclined at a large angle from the axis of material rotation, and which precesses about it. Isaak contends that this perturbation is produced by an internal oblique magnetic rotator of a kind proposed previously by Dicke[3,4].

Both the magnetic effects and the rotational effects are small, producing frequency changes of $<0.1\%$. Therefore, as Isaak[2] acknowledged, it is quite adequate to linearize about the nonrotating nonmagnetic state, and treat the two perturbations separately. To this end it is conceptually convenient to work in a frame S' rotating with the magnetic field, say with angular velocity Ω_0, and transform to the inertial frame later. In S' the equilibrium state is steady, and the oscillations about that state can be described by eigenfunctions that are separable in space and time. I shall assume, with Dicke[3], that the field has an axis of symmetry, in a direction (Θ, Φ) with respect to an inertial coordinate system S whose axis coincides with the axis of rotation. The axis of magnetic symmetry is taken as the axis of spherical polar coordinates (r, θ', ϕ') in S'. With respect to these coordinates the angular order of a mode will be denoted by m'.

Perturbation theory for magnetic stars has been developed by Ledoux and Simon[22], and subsequently by Goossens[23]. Both the equilibrium state and the normal modes of oscillation are expanded in powers of a parameter λ, which characterizes the strength of the Lorentz force in relation to the pressure gradient; it measures both the deviation from spherical symmetry of the equilibrium configuration and the perturbation to the eigenfrequencies. In the Sun λ is small: if, for example, the magnetic field is confined to the core, and has intensity 5×10^7G, then $\lambda \simeq 10^{-3}$. Since the postulated magnetic field is buried in the solar interior, singular perturbations in the surface layers[24,25] are of no consequence.

Consider first the perturbation to the shape of the dipole wave pattern. Formally, the most striking effect of the magnetic field is to resolve the degeneracy in the eigenfunctions. The dipole oscillations are separated into three well-defined modes, however weak the field. But that does not change the number of peaks in the power spectrum. A new peak associated with the $m=0$ mode resulting from a modification to the geometry of the wave pattern can come about only by coupling to a mode of even degree l^*. If ω^* is the frequency of free oscillation of the coupled mode that is nearest to ω, the ratio of the amplitude of the coupled mode to that of the dipole mode is of order $\sigma = \min(1, \lambda\omega/|\omega-\omega^*|)$. If $l^*=0$ or $l^*=2$, $|\omega-\omega^*| \simeq 70$ μHz. Then $\sigma \simeq 40\lambda$, which is probably too small for the coupled mode to be detected. If $l>2$ it is conceivable that a chance resonance could make $\sigma = 0(1)$, but in that case the sensitivity of the observations is too low to account for the observed central peak[17]. Similar arguments apply to the quadrupole modes. Therefore the most significant influence the magnetic field is likely to exert is to change the speeds of propagation of the waves.

At this juncture it should be pointed out that any standing dipole mode has an axis of symmetry, and can be represented as a linear combination of the three modes with $l=1$. If somehow that pattern could be caused by the rotating magnetic field to rotate with angular velocity Ω_1 about the axis of the inertial frame S, the sole effect would be to augment the frequencies of the three components in S by $m\Omega_1$. After adding the effect of material rotation, the frequencies of the modes would become $\omega_0 + m(\Omega_1 + \bar{\Omega})$. This, of course, is completely analogous to, and observationally indistinguishable from, rotational splitting, and therefore could not introduce another component to the power spectrum.

The effect of the magnetic field $\mathbf{B}$, however, is not to induce a simple rotation of a standing mode. Because the Lorentz force is quadratic in the field, changing the sign of $\mathbf{B}$ has no effect. Hence there is no distinction between waves propagating positively and negatively about the axis of symmetry. Though frequency changes can depend on the magnitude of m', they cannot depend on its sign. In S', combinations of modes with like $|m'|$ yield standing waves that do not precess; but unlike rotationally split modes, the frequency splitting is sensitive to m', at least when l is small. It is an immediate corollary that to leading order in λ the frequencies observed are not influenced by the angular velocity of the buried magnetic field configuration: as is evident in equation (4), after adding the effect of rotation and transforming to the inertial frame (or, for that matter, to any other rotating frame that does not depend on Ω_0, such as the frame rotating with the Earth), Ω_0 cancels.

It is not inconceivable, however, that an observable dipole triplet could be induced by a magnetic field. Let us represent any mode of degree l by a superposition of the modes in S' of degree l and angular orders m'. Then the effect of the field is to augment the frequencies by $\delta_{m'}\omega$, say, where $\delta_{-m'}\omega = \delta_{m'}\omega$. After transforming the modes to S, and adding the effect of rotation, each component (l, m) is found to have multiple frequencies. These are listed in Table 1 for the dipole modes. Since in this case the $m=0$ modes cannot be detected, there are four frequencies that should appear in the spectrum. It is possible, however, to reduce these to a triplet, if the two inner components have identical frequencies. This occurs if

$$|\delta_1\omega - \delta_0\omega| = 2\beta\bar{\Omega} \qquad (6)$$

The frequency splitting is then $2\beta\bar{\Omega}$, which is again consistent with almost uniform rotation.

The hypothesis raises several issues. For example, condition (6) is a relationship between the magnetic field and the rotation, and was engineered to force agreement with observation. If it were satisfied in the Sun, it would be unlikely to be accidental. We know, of course, that there is a dynamical connection between Ω and $\mathbf{B}$. But why should it be such that particular oscillation frequencies coincide, especially since the energy in the oscillations is very much less than the field energy? Moreover, we must acknowledge that $\delta_{m'}\omega$ might vary with frequency, and question whether equation (6) can be satisfied sufficiently well by all the relevant modes. The observations would therefore set limits on how rapid the variation could be. There are also further conditions, analogous to equation (6), to be explained. They arise from demanding that quadrupole modes are split into only quintuplets. These would constrain Ω and $\mathbf{B}$ further.

It is also of interest to compare the amplitudes of the components of the multiplets. It can be shown that if the three dipole modes in S' have r.m.s. displacement amplitudes $A_{m'}$ in the atmosphere, the mean squared amplitudes in S, in ascending or descending order of frequency according to whether $\delta_1\omega$ is

Table 2 Frequency shifts (μHz) of those high-order solar quadrupole p modes that can be detected by whole-disk observations

m'	$m=-2$	$m=0$	$m=+2$
0	0.91	1.68	2.45
1	3.08	3.85	4.62
2	1.56	2.33	3.10

Observations are referred to a frame rotating with the Earth about the Sun and computed assuming the presence of a toroidal magnetic core chosen so as to reduce the dipole quadruplet to a triplet. Rotational splitting was computed from equation (5) with $\alpha = 0.2$.

greater or less than $\delta_0\omega$, should be in the ratios

$$A_0^2 \sin^2\theta :$$
$$A_0^2 \sin^2\theta + \tfrac{1}{2}(A_1^2 + A_{\bar{1}}^2)(1 - \tfrac{1}{2}\sin^2\theta) :$$
$$\tfrac{1}{2}(A_1^2 + A_{\bar{1}}^2)(1 - \tfrac{1}{2}\sin^2\theta) \tag{7}$$

Because the whole-disk observations are equally sensitive to modes with $m = -1$ and $m = +1$, these represent the ratios of the power in each peak of the triplet. Note that whatever the values of $A_{m'}$ and θ, the power in the central peak is the sum of the powers in its two neighbours. This appears not to be in accord with observation[1].

The magnetic core postulated by Dicke[3,4] is presumed to have been formed by field stretching produced by the differential rotation. This created an essentially toroidal field, about an axis which subsequently departed from the Sun's rotation axis, in a manner that has been discussed by Mestel *et al.*[26–28]. Now it lies almost in the equatorial plane, with $\theta = 86°$. I approximate the magnetic field by

$$\mathbf{B} = (0, 0, B(r)\sin\theta'\cos\theta') \tag{8}$$

without questioning its stability. This is the form originally adopted by Dicke[3], though a subsequent analysis of the oblateness data suggests a more complicated configuration[29].

The perturbations $\delta_{m'}\omega$ generated by $\mathbf{B}$ can be computed using Goossens's analysis[23]. In the limit of high-order p modes the result is

$$\delta_{m'}\omega \sim \frac{(2l+1)}{u(R)}\frac{(l-|m'|)!}{(l+|m'|)!}\left[\!\!\left[\int_0^R \left\{a\left[\frac{\mathrm{d}}{\mathrm{d}r}(r\xi B)\right]^2 + bm'^2\xi^2B^2\right\}\mathrm{d}r \right.\right.$$
$$\left.\left. - \frac{\omega}{4\pi}\int_0^R \mathrm{d}r\int_0^\pi c^{-1}(c_1^2 - \varepsilon)[P_l^{m'}(\cos\theta')]^2\sin\theta'\,\mathrm{d}\theta'\right]\!\!\right] \tag{9}$$

where

$$u = \int_0^r c^{-1}\,\mathrm{d}r \tag{10}$$

$$\xi = r^{-1}\rho^{-1}c^{-1}u^{1/2}J_{l+3/2}(\omega u) \tag{11}$$

$$a(l, m) = \int_{-1}^{1} [P_l^{m'}[(\mu)]^2\mu^2(1-\mu^2)\,\mathrm{d}\mu,$$

$$b(l, m') = \int_{-1}^{1} [P_l^{m'}(\mu)]^2\mu^2\,\mathrm{d}\mu \tag{12}$$

$\rho(r)$ is the density of the equilibrium model in the absence of $\mathbf{B}$, and J_ν is the Bessel function of the first kind. The variable c_1^2 is the small θ'-dependent part of the square of the adiabatic sound speed in the equilibrium configuration, measured in units of c^2, and $\varepsilon(\theta')$ is such that $r = (1+\varepsilon)R$ defines the equilibrium photosphere. The first integral in equation (9) represents the direct effect of the Lorentz force on the oscillations, and the second integral results from the axisymmetrical distortion to the equilibrium state.

It can now be argued that an intense large-scale magnetic field cannot pervade the entire radiative region of the Sun. If there were such a field, all the terms in the integrals in equation (9) would be of roughly the same magnitude. According to Dicke[3–9] ε is of order 3×10^{-5}, and according to Hill *et al.*[28] it must be even smaller. This sets an upper limit to the intensity of the magnetic field. It implies that the magnitude of $\delta_{m'}\omega$, to within a factor of order unity, can be no larger than $3\times10^{-5}\omega$, which is too small for equation (6) to be satisfied.

The distortion associated with a field confined to the core is relatively small at the photosphere. This permits the field to be stronger without it being ruled out by the oblateness measurements. Can it be strong enough to produce the frequency shift required? Note first that the contribution to $\delta_{m'}\omega$ from the distortion of the equilibrium structure is proportional to ω. Therefore, if that term dominated, it would not be possible to satisfy equation (6) over the entire frequency range. Admittedly, a variation of only 30% in ω is sufficient to encompass half the power in the spectrum of the 5-min modes, and such a variation in the splitting cannot convincingly be ruled out by the published data[1]. Nevertheless, in anticipation that cleaner results will be obtained in the future, I shall simplify the analysis by ignoring the second integral. Moreover, I shall choose a field amplitude $B(r)$ to render the first integral only weakly dependent on ω.

In the core, the major variation of ξ is produced by the Bessel function. Its argument is proportional to ω, and, in particular, the radius of the first node is roughly inversely proportional to ω. Since B is independent of ω, and ξ and B occur in the expression for $\delta_{m'}\omega$ only in the combination ξB, it follows that $\delta_{m'}\omega$ is stationary with respect to ω when ξ and B overlap maximally, in an appropriate sense. Therefore the variation of $\delta_{m'}\omega$ with ω can be made weak if B and ξ are similar functions at the median frequency $\bar{\omega}$. As an example, I choose

$$B(r) = \begin{cases} B_0 r\rho c u^{-1/2}J_{5/2}(\bar{\omega}u), & \bar{\omega}u \leqslant j_{5/2} \\ 0, & \bar{\omega}u \geqslant j_{5/2} \end{cases} \tag{13}$$

with $\bar{\omega}/2\pi = 3$ mHz and B_0 constant. Here j_ν is the first zero of J_ν. The factors in front of the Bessel function were chosen just for analytical convenience. The function $B(r)$ has a single maximum, near $r \simeq 0.14R$, and falls to zero at $r \simeq 0.22R$.

It is a straightforward matter to evaluate the frequency shifts $\delta_{m'}\omega$, and hence compute B_0 by insisting that the constraint (6) be satisfied at $\omega = \bar{\omega}$. The result is such that the maximum value of $B(r)$ is 1.1×10^8 G, which implies a total field energy of 3.5×10^{45} erg. This is to be compared with a similar field suggested by Dicke[3], which had been chosen to explain his oblateness data. That field extends to $r \simeq 0.33R$ and has a maximum value of 6.1×10^7 G at $r \simeq 0.16R$. Dicke does not exhibit the radial dependence of his field precisely, but if it were taken to be homologous to $B(r)$, the energy would be 3.6×10^{45} erg. Such a field is apparently incompatible with the oblateness data of Hill *et al.*[28].

The stationary value of the first integral in equation (9), with respect to variations in ω, is a minimum. Consequently, amongst function B generated from equation (13) by varying $\bar{\omega}$ and B_0 such as to preserve equation (6), 1.1×10^8 G is a maximum of the field strength.

Consider now the quadrupole modes. With respect to the coordinate system in S, only modes with $m = 0$ and $m = \pm2$ should be detectable in the whole-disk data. As with the dipole modes, the frequencies are split by rotation. Furthermore, the magnetic field splits the frequencies for each value of m in to three, corresponding to the three different values of $|m'|$. Consequently, there are nine, not five potentially observable components in the power spectrum. Table 2 lists the synodic deviations of those nine frequencies from ω_0, computed with that value of B_0 that reduces the dipole frequencies to a triplet. Note that there are three pairs of frequencies that are too close to have been resolved by Claverie *et al.* Thus there should be no more than six observable components, with median frequencies 0.91, 1.62, 2.39, 3.09, 3.85, 4.62 μHz above ω_0. These frequencies are nearly uniformly distributed, with a mean spacing of 0.74 μHz.

The coincidences of some of the quadrupole frequencies arise because the magnetic splittings $\delta_{m'}\omega - \delta_{m'-1}\omega$ of the modes are roughly integral multiples of the dipole splitting. The difference between the dipole and quadrupole eigenfunctions ξ is not very great in the core, so the integral of $[\mathrm{d}(r\xi B)/\mathrm{d}r]^2$ in particular is similar for the two values of l. That integral exceeds the integral of ξ^2B^2 by a factor of ~10. Therefore the near commensurability of the splittings is largely a product of the properties of the spherical harmonics, and is not dependent on the detailed structure of the function $B(r)$. Thus if the magnetic field in the solar core is intense enough to produce observable splitting, and is such as to reduce the expected dipole quadruplet to a triplet, then it is likely that the quadrupole frequencies constitute only a sextuplet, with a mean separation that is roughly the same as for the dipole triplet.

I have shown that some aspects of the Birmingham data might be rationalized if the Sun were to have an intense magnetic core; so might the Princeton oblateness data. However, that does not imply that the magnetic core exists. Aside from the contradiction by the oblateness measures of Hill *et al.*[30], there would be disturbing conflicts with certain properties of the oscillations. These may eventually be decisive. The incorrect ratios of the amplitudes of the dipole triplet, for example, would demand explanation, as would the absence of a component of the predicted quadrupole sextuplet. In superposed spectra such as those presented by Claverie *et al.*[1], it is hardly likely that some peaks are removed by interference. Nevertheless, there is the possibility that a magnetic field configuration rather different from that considered here could produce a quintuplet. Notice that in that case the splitting would still be $2\beta\Omega$, implying $\bar{\Omega} \simeq \Omega(R)$.

The high energy in the magnetic field would also need explaining. That energy is probably 50 or more times greater than the kinetic energy in the solar rotation today, though when the intense field was presumed to have been created the rotational energy may have been more than 1,000 times greater than its present value. Nevertheless, it would still be necessary to demonstrate that the regeneration of magnetic field by the differential rotation of the core, if it occurs, is sufficient to balance dissipation by instabilities.

And finally, what of the rotation itself? The potential explanation of the dipole triplet discussed here requires that the mean solar angular velocity, weighted by the reciprocal of the sound speed, is hardly different from the surface value. That is not easy to reconcile with the 12.2-day period of the core required by Dicke to explain the periodic component in his oblateness data. Moreover, it appears to be contradicted by the analyses of apparent rotational splitting inferred from oscillations in the limb-darkening function[31,32], which suggests that Ω is some six times greater at the centre of the Sun than it is at the surface. The condition $\bar{\Omega} \simeq 2\Omega(R)$ claimed by Claverie *et al.*[1] and Isaak[2] is not inconsistent with that result. Thus it seems likely that the solar magnetic field is not strong enough to have produced the splitting required to satisfy equation (6). Therefore the explanation for the fine structure in the whole-disk power spectrum needs still to be found and demonstrated, and until that is accomplished one cannot be confident that the separation of the multiplets results solely from rotational splitting.

VHF Faraday polarization fluctuations and strong *L*-band amplitude scintillations near Appleton anomaly crests

A. DasGupta*, M. C. Lee† & J. A. Klobuchar*

The Faraday rotation angle of a linearly polarized transionospheric very high frequency (VHF) signal near the crests of the Appleton anomaly, around the recent solar maximum period, often exhibits fast and intense fluctuations, when the amplitude of the signal shows saturated and very fast scintillations[1,2]. These fluctuations usually occur during the post-sunset hours and decay around midnight. The occurrence pattern has been found to be similar to that of microwave amplitude scintillations at *L*-band. We present here certain observed characteristics of the fast polarization fluctuations and report the results of an experiment, which shows that there is a loss of correlation between fadings on the two circularly polarized component modes of the signal during the periods of VHF polarization fluctuations. Hence, the usual concept of Faraday rotation is no longer valid during these times. The above features are discussed in terms of our present knowledge of small scale irregularity structures in the equatorial ionosphere.

Equatorial ionospheric irregularities have been extensively investigated during the past decade by techniques such as rocket and satellite *in situ* measurements, radar, airglow and propagation effects on transionospheric signals[3]. It has been shown that the plumes of equatorial irregularities associated with depletions in background electron content can be studied in a very simple and inexpensive manner from simultaneous measurements of amplitude scintillations and Faraday rotation of a VHF signal propagating through the ionosphere[4,5]. While the occurrence of depletions of the integrated electron content is commonly observed with Faraday rotation records obtained near the magnetic equator[6,7], a new feature, fast and intense fluctuations of the Faraday rotation angle, has recently been reported from stations situated near the crests of the Appleton anomaly[1,2], a region characterized by severe amplitude scintillations during solar maximum years[8,9]. Polarization fluctuations of 136-MHz signals have been observed at Ascension Island (31°S dip), which is situated close to the southern crest of the equatorial anomaly in the African zone, and at Calcutta (32°N dip) and Ahmedabad[10] (34°N dip) near the northern crest of the anomaly in the Indian sector. These have sometimes been observed even at Delhi (40°N dip) (Y. V. Somayajulu, personal communication) near the northern edge of the anomaly, but no such phenomenon has been observed at Arequipa (9°S dip), Peru or at Natal (10°S dip), Brazil which are close to the magnetic equator. Kaushika and deMendonca[11] possibly observed the same type of fluctuations in the polarization records of 137-MHz signals recorded at Sao Paulo (26° S dip) which is also situated near the crest of the anomaly, but they had no amplitude scintillation measurements. In their attempt to associate the fluctuations with atmospheric gravity waves, they were concerned with slower fluctuations of period 2 min and longer.

Figure 1 shows a typical polarimeter record obtained during post-sunset hours at Ascension Island (7.9° S, 14.4° W, 31° S dip). The channel at the top is the amplitude of the 136-MHz transmission from the geostationary satellite SIRIO (15° W) and the two bottom channels are the Faraday polarization angle of the signal with one shifted from the other by 90°. The polarization fluctuations are often too intense to render the Faraday data useful. The station also recorded signals from the

0028–0836/82/290354—04$01.00

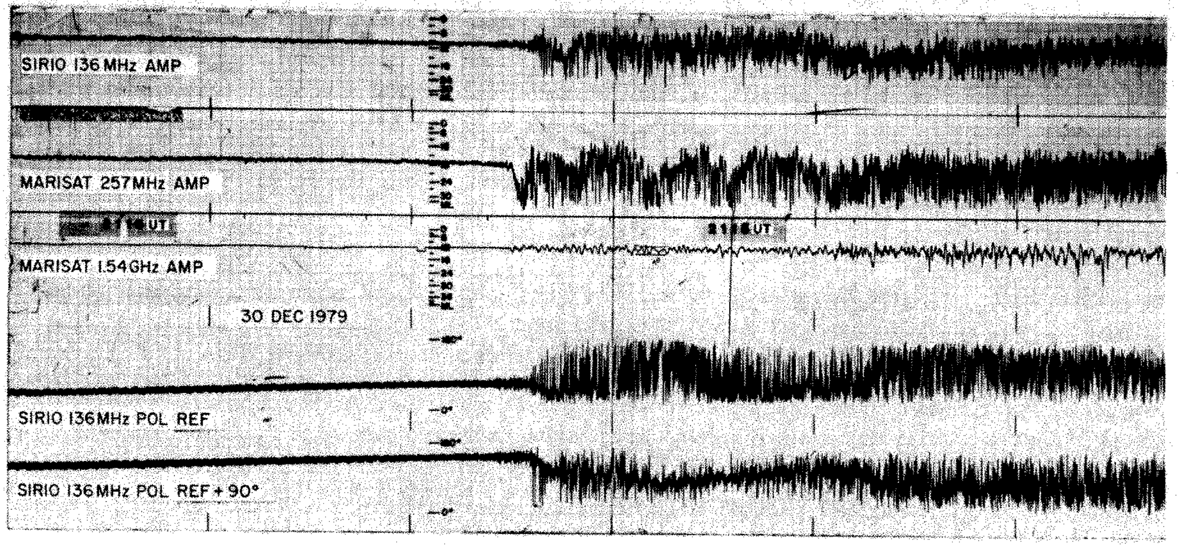

Fig. 1 Sample records of satellite signals obtained at Ascension Island. Time marks shown are in UT. Local time corresponds to UT − 1 h.

satellite Marisat (also at 15° W) at 257 MHz and 1.54 GHz for amplitude scintillation measurements. The sub-ionospheric points of the two satellites are essentially identical. The third channel from the top shows amplitude scintillations of the 1.54-GHz signal. Polarization fluctuations are found when the amplitude of the VHF signal shows saturated and very fast scintillations, which generally occur during the pre-midnight hours. We have found during more than 2 yr of observations around the recent solar maximum period that the polarization fluctuations coexist with intense *L*-band scintillations at 1.54 GHz. During the post-midnight period polarization fluctuations decay, even though VHF amplitude scintillation remains saturated, but with slower fading rates.

The change in fading rates of VHF amplitude scintillations, with and without polarization fluctuations, is clearly evident in the power spectra of 136-MHz scintillation measurements as presented in Fig. 2*a* and *b* respectively. The corresponding power spectra obtained at 257 MHz and 1.54 GHz are also shown. The approximate corner frequencies of the power spectra are indicated by arrows. The corner frequency of a power spectrum gives a measure of the fading rate, a higher corner frequency corresponding to a faster fading rate. In the present case, a lowering of the corner frequency is obvious in the late phase, as shown in Fig. 2*b*, when no polarization fluctuations are observed.

Power spectrum analysis of scintillation measurements is generally used to obtain information on the characteristics of the ionospheric irregularities responsible for scintillations. However, the interpretations of the power spectrum in conditions of weak and strong scintillations involve different scattering mechanisms by the ionospheric irregularities. According to the theory of radiowave propagation, for weak scintillation conditions, the amplitude fading rate of a transionospheric signal from a geostationary satellite is proportional to v/l_F, where v is the drift velocity of the irregularities and l_F the Fresnel dimension[6]. Because $l_F \propto \sqrt{\lambda}$ (where λ is the radiowave length), the fading rate should increase with observing frequency in weak scatter conditions. In contrast, in the case of severe scintillations, the wave propagation has to be considered in the framework of multiple scatter theory and the recorded scintillation data pertain to the ground diffraction pattern, which cannot be related to the irregularity pattern in the ionosphere in a simple manner[12]. The fading rate, in severe scintillation conditions, is inversely related to the autocorrelation distance of the ground pattern. The autocorrelation interval is determined by the drift velocity as well as by the strength of scattering. As the strength of scattering (in other words, scintillation index) increases, the autocorrelation distance decreases[13], and an increase in the fading rate is observed[14]. The scintillation index is usually inversely related to the observing frequency. Thus, in the case of severe scintillations, with an increase of the observing frequency the autocorrelation distance should increase and hence, a slowing down of the amplitude fading rate occurs.

In the equatorial region amplitude scintillations observed at 136 MHz and 250 MHz are usually severe (saturated or near saturated) for most of the time the phenomena are observed. Near the crests of the Appleton anomaly, severe scintillations in excess of 20 dB are quite frequent even at *L*-band (such as 1.54-GHz observations at Ascension Island) during the pre-midnight hours, particularly around the recent solar maximum[8]. The power spectra depicted in Fig. 2 are representative of scintillations observed at the corresponding frequencies in the developed and late phases of equatorial night-time ionospheric irregularities respectively.

During an intensive campaign of measurements in December 1979, in order to investigate the nature of fast polarization fluctuations, the left and right circular components of the 136-MHz signal were recorded separately in addition to the routine observations. The data were recorded on a magnetic tape in analog form, which was digitized at an 18 samples s^{-1} rate for later analysis. The cross-correlation between the amplitude fadings of the two component modes was computed over 3-min intervals. The scintillation index S_4 (refs 15, 16), which is a measure of the r.m.s. amplitude fluctuations about the mean level, is also computed for each 3 min interval at different observing frequencies. Figure 3 shows the variation of the cross-correlation coefficient between the amplitude fadings of the two circularly polarized component waves at 136 MHz with changes in the scintillation index S_4 observed at 1.54 GHz.

The correlation coefficient decreases as S_4 increases and attains low values (<0.2) when S_4 is 0.5 or more. The intervals with $S_4 > 0.5$ at 1.54 GHz generally exhibit fast polarization fluctuations at 136 MHz. In other words, the two circularly polarized components undergo quasi-independent fluctuations when strong *L*-band and polarization fluctuations are obtained. If the two modes become quasi-independent, the usual concept of Faraday rotation breaks down. The close correlation of occurrence of 136-MHz polarization fluctuations and the 1.54-GHz scintillation, clearly seen in Fig. 3, implies that either irregularities of nearly the same scale size are responsible for the two phenomena or that the irregularities causing the two phenomena coexist in the ionosphere.

Lee *et al.*[17] have shown that ionospheric power law density irregularities with an outer scale size in the range 50–200 m are responsible for the 136-MHz polarization fluctuations. Faraday polarization fluctuations result from differential phase shift and the differential change in the logarithmic amplitude of the two circularly polarized modes introduced by wave scattering from these short-scale density irregularities. The theory

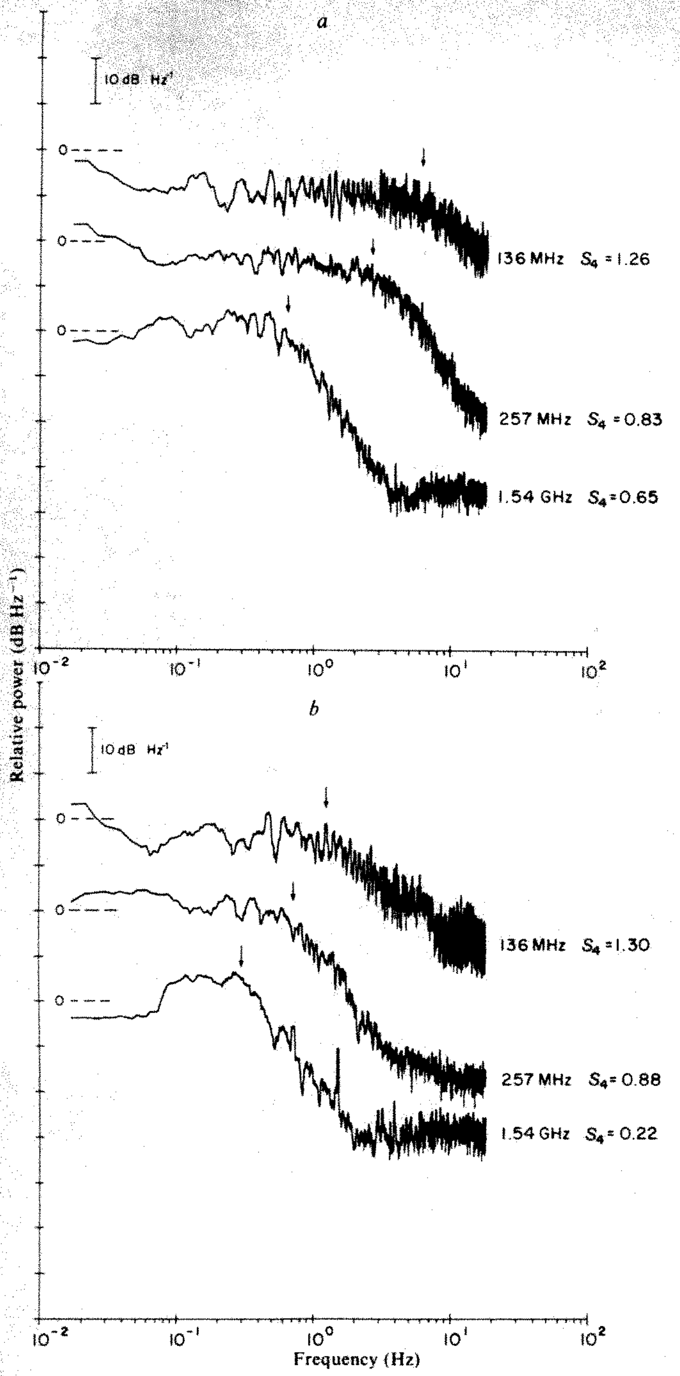

Fig. 2 Power spectra of amplitude scintillations at different frequencies for a 3-min sample centred on the time indicated. *a*, 21 h 46 min 30 s UT; Faraday polarization channels show intense and rapid fluctuations during this period. *b*, 22 h 34 min 30 s UT; no fast polarization fluctuation was observed during this period. The approximate corner frequencies are given by arrows.

shows that a deviation of ~1–2% in a high ambient ionization density, say, not less than $3.0\times10^{12}\,\mathrm{m}^{-3}$, corresponding to a plasma frequency of over 15 MHz, is required to provide a favourable environment for the 136-MHz fluctuations to occur. When the r.m.s. differential phase departure exceeds ~0.5 rad, the two circularly polarized modes are expected to become practically uncorrelated. Scintillations at 1.54 GHz are most effectively produced by irregularities with scale sizes of a few hundred metres (~300 m in the present case), which are of the same order as the Fresnel zone dimension. Both the 136-MHz polarization fluctuations and the 1.54-GHz scintillations involve density irregularities of a few hundred metres scale size. If the irregularity power spectrum follows a power law, with diminishing spectral density at shorter scale lengths, and if the overall strength of the irregularities is high enough to have spectral density in the 50–200 m scale size range sufficient to cause polarization fluctuations at 136 MHz, it is implied that irregularities at a ≳300 m scale size range will also have enough spectral power to produce appreciable amplitude scintillations at 1.54 GHz. Thus, the presence of fast polarization fluctuations at 136 MHz may be taken as an indication of the possible scintillations at *L*-band and lower frequencies. The reverse may not, however, always be true.

From multi-technique observations Basu *et al.*[18] have reported that, while during the pre-midnight period the power spectra of equatorial irregularities follow a power law, during post-midnight hours the overall strength of the irregularities is eroded and there is a transition to a quasi-gaussian type of spectrum indicating the decay of shorter-scale (typically <1 km) irregularities. As the 1.54-GHz scintillation became weak, with the decay of short-scale density irregularities, the two circularly polarized modes were seen to have high cross-correlation coefficients, reflecting no, or very small, polarization fluctuations.

Except in the HF band (for example, 20 MHz), the polarization fluctuations of satellite signals cannot be effectively caused by irregularities with quasi-gaussian spectra[19]. Near the Appleton anomaly crests, in solar maximum conditions, the ambient ionization density (n) is very high and the high level persists during the evening hours. As a result, the absolute value of the irregularity intensity (Δn) is also very high in the anomaly region[8]. In contrast, in regions near the magnetic equator, the relatively small n and Δn and the relatively large angles of propagation with respect to the geomagnetic field make it impossible to give rise to significant polarization fluctuations of 136-MHz signals[17].

Is the olivine–spinel phase transformation martensitic?

P. J. Vaughan & H. W. Green II

California 95060, USA

Olivine, the dominant mineral in the Earth's uppermost mantle, undergoes one, or possibly a series of phase transformations to adopt a spinel structure at pressures above ~13 GPa. The mechanism by which the transformation is accomplished could have important implications for understanding mantle dynamics and deep focus earthquakes. Recently, it has been proposed that the transformation may proceed by a martensitic mechanism[1–5]. We discuss here the characteristic properties of martensitic transformations and present evidence that the analogous transformation in Mg_2GeO_4 does not proceed by such a process.

Polymorphic transformations which occur by a martensitic mechanism involve a specific, coordinated movement of atoms. The interface which effects the transformation propagates by the movement of a series of partial dislocations resulting in the production of stacking faults. Such faults represent monolayers of the new phase[6]. This process contrasts with the nucleation and growth mechanism in which the interface propagates by a generally uncoordinated, thermally activated movement of atoms. Martensitic transformations involve a significant shear component in their transformation strain. This means that if the transformation is accomplished under nonhydrostatic stress, the process should be enhanced in favourably oriented parent crystals and retarded in unfavourably oriented parents. Higher stresses (and hence strain rates) will favour the transformation. The daughter phase generally grows as lamellae in the parent, whereas the nucleation and growth mechanism usually produces irregular interfaces due to more rapid migration in directions of greater stored strain energy in the deformed parent. Martensitic mechanisms always exhibit specific crystallographic relationships between parent and daughter crystals, whereas nucleation and growth (also proposed for olivine–spinel[7]) can, but normally does not, produce such relationships. The topotactic relation required by the martensitic mechanism proposed for the olivine–spinel transformation is $[100]_{ol}$ parallel to $\langle 111\rangle_{sp}$ and $[001]_{ol}$ parallel to $\langle 011\rangle_{sp}$ (refs 3,4). This crystallographic relationship has been reported in a few instances in Fe_2SiO_4 (ref. 3) and Ni_2SiO_4 (ref. 5); in the latter case only 3 out of 10 spinel crystals showed the exact relationship, and 5 showed large deviations. The occasional presence of topotaxy is compatible with any transformation mechanism, but it must be present in all instances to support the martensitic mechanism.

The olivine–spinel transformation for the chemical composition appropriate for the Earth's mantle, $(Mg_{0.9}, Fe_{0.1})_2SiO_4$, has been very difficult to study directly due to the very high transformation pressure[8,9]. Consequently, the transformation has been studied in other systems, principally Fe_2SiO_4, (ref. 3), Ni_2SiO_4 (ref. 5) and Mg_2GeO_4 (ref. 10), which undergo the transformation at lower pressures. Although systematic studies of these and other analogues have shown very great similarities between the various systems, one complication remains. Each of the analogue systems listed above undergoes the transition directly, whereas for the Mg-rich silicate olivine system there is another (β) phase with a distorted-spinel structure which is found at intermediate pressures[8,9]. Transmission electron microscopy (TEM) studies[1,2,11] indicate that in many cases the β-phase may be a quench product formed at the expense of the γ-phase. Considering these uncertainties, the simplest approach regards the direct transformation (olivine–spinel) as relevant to the mantle[12]. The martensitic mechanism was proposed on this basis and the topotactic relations found in Fe_2SiO_4 and Ni_2SiO_4 have been cited as support for the martensitic mechanism on the same basis. We continue this approach here while recognizing that the question of relevance to the mantle remains unresolved until the mineralogy is better known.

To test the martensitic hypothesis, we selected a deformed Mg_2GeO_4–olivine sample which had partially transformed to spinel. The run conditions of this creep experiment (no. 92) were: confining pressure, $P = 1.3$ GPa; average differential stress, $\sigma = 280$ MPa; total axial strain 5%; duration 55 h (ref. 11). The temperature along the 18.4-mm long sample varied from 950 °C at the lower end to 1,200 °C in the centre. Thus, the lower portion of the sample was well within the spinel field but the central portion was just inside the olivine field. Specimens were selected from a small region of 50–60% spinel near the lower end of the sample. TEM foils were prepared by

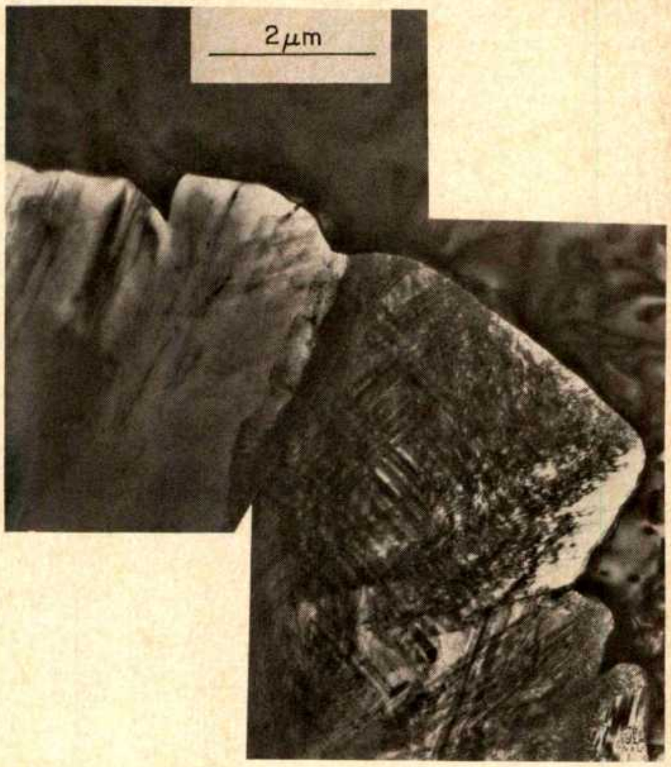

Fig. 1 High-voltage transmission electron micrograph of large spinel grains with a high density of stacking faults and parent olivine with moderate dislocation density (800 kV). The maximum compressive stress applied to the specimen lies NE–SW, parallel to the spinel–spinel grain boundaries.

0028–0836/82/290357—02$01.00

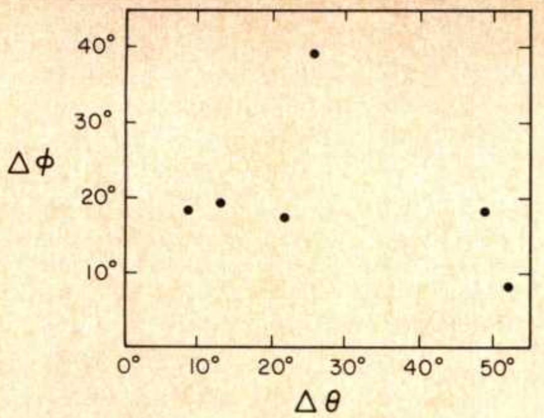

Fig. 2 Diagram showing the deviation from the orientations predicted for the martensitic transformation mechanism. $\Delta\theta$ measures the angle between $[100]_{ol}$ and the nearest $\langle 111\rangle_{sp}$; $\Delta\phi$ is the angle between $[001]_{ol}$ and the nearest $\langle 011\rangle_{sp}$. Data were obtained by selected area electron diffraction.

ion-thinning and examined in both optical and electron microscopes.

The following observations on this specimen suggest that the mechanism of the transformation was not martensitic:

(1) TEM images display no stacking faults in the olivine phase (Fig. 1); the substructure, both near to and far from olivine–spinel interfaces, is that normally produced during plastic deformation of germanate[13] and silicate[14] olivine. Thus, there is no direct evidence for operation of the martensitic mechanism. Stacking faults appear in the spinel phase (Fig. 1), but there is no indication that they are involved in the transformation process[15].

(2) Variations in the diffraction contrast images of the daughter spinel crystals growing into the same olivine parent grain indicate that the spinels have different orientations (Fig. 1). Moreover, selected-area electron diffraction of several parent–daughter clusters demonstrates that the topotactic relations required by the martensitic mechanism are not present (Fig. 2). Small deviations from topotaxy might be explained away as loss of coherency by accumulation of dislocations in the interface. However, the lack of evidence for the required dislocations and the extremely large deviations from coherency (Fig. 2) render such an argument untenable.

(3) The spinel crystals have an elongated growth habit, but the inequant shapes are independent of the crystal orientation of both olivine and spinel. The martensitic mechanism requires a crystallographic relationship and preferential growth of spinel in olivine crystals oriented with high shear stress on the hypothetical dislocations which effect the transformation.

(4) The spinel crystals have grown preferentially in the direction of the maximum compressive stress, resulting in subparallel fingers of spinel separated by residual spikes of olivine (Figs 1 and 3).

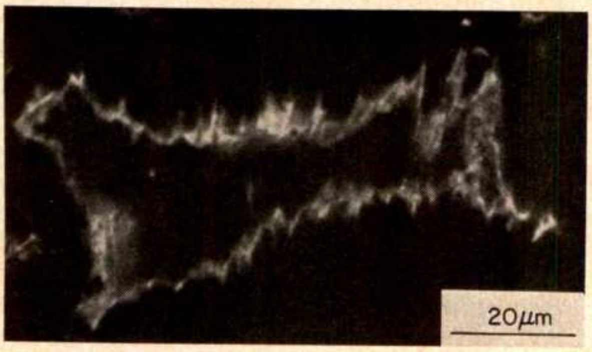

Fig. 3 Optical micrograph of a residual olivine grain surrounded by spinel. The prominent north–south spikes protruding from the olivine crystal are the remnants left between spinel grains which have grown preferentially parallel to the maximum compressive stress (crossed polarizers).

We have failed to find any evidence indicative of a martensitic transformation. On the other hand, the observation that the spinel displays a strong growth anisotropy reflecting the stress field is an interesting new discovery. This is consistent with a simple nucleation and growth mechanism in which the driving force for growth varies with the $P\Delta V$ term in the equation describing the difference in Gibbs free energy between the two phases (ref. 16, and work in preparation).

Noise in chaotic systems

John Guckenheimer

Division of Natural Sciences, University of California, Santa Cruz,
California 95064, USA

Procedures which estimate the noisiness of complicated, aperiodic data are outlined here and considered in the context of transitional fluid flow, although similar questions arise in many other fields[1,2]. Because this is the initial formulation of these ideas only qualitative results are presented; any attempt to develop quantitative measures of randomness will be postponed until more testing and refinement of the procedures have been completed.

Consider a fluid experiment such as Rayleigh–Bérnard convection or the flow between concentric cylinders in a regime which produces aperiodic flow[3]. Substantial theoretical and experimental attention has been given to the temporal characteristics of these flows as dynamical systems. The Landau–Hopf model of turbulence[4] portrays turbulent flow as quasiperiodic with many independent frequencies. This view was successfully challenged by Ruelle and Takens[5] with an argument based on the structural instability of quasiperiodic attractors for dynamical systems. Extensive high-precision experiments have demonstrated that the transition to aperiodic flow occurs directly from flows whose power spectra have few independent frequencies[6,7]. These measurements for small aspect ratio fluid experiments are evidence that fluid transitions in this regime are described reasonably well by the bifurcations of systems of differential equations with few degrees of freedom[8]. There is still disagreement, however, as to whether the aperiodicity of the post-transition flows has the characteristics which one finds in a trajectory of a system of ordinary differential equations with a state space of low dimension. In particular, it has been suggested that some aspects of the data are described much better by stochastic models. The methods proposed here may help resolve this matter.

Dynamical systems with few degrees of freedom can have 'strange attractors': bounded sets of aperiodic trajectories which are asymptotically stable[10,11]. Some features of a trajectory in

0028–0836/82/290358—04$01.00

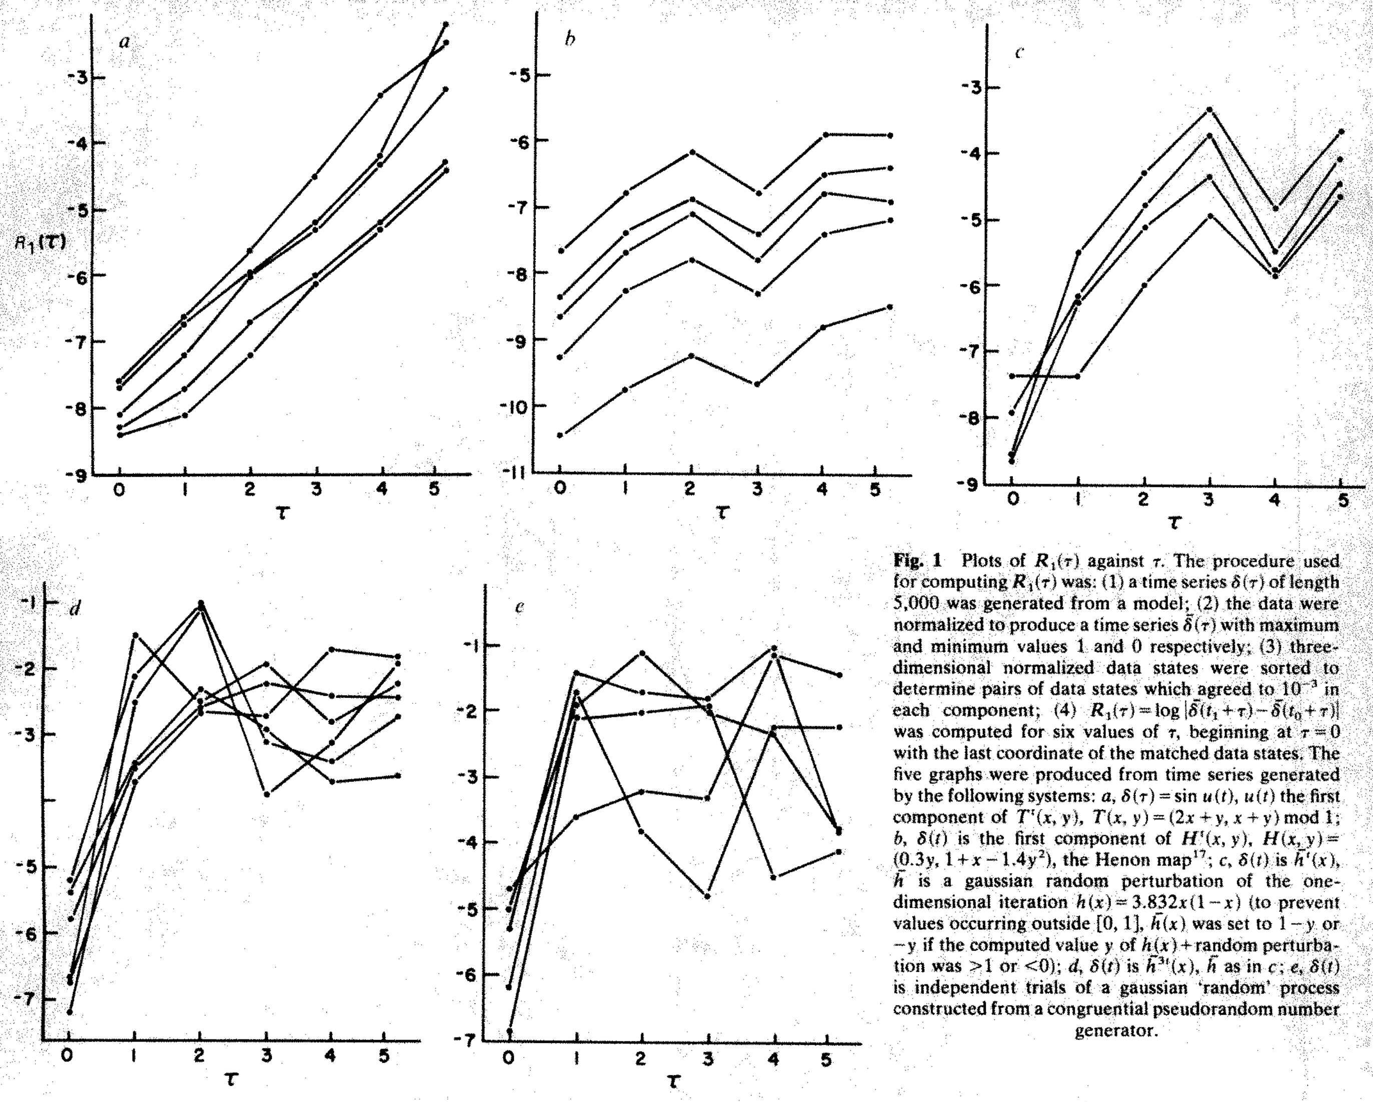

Fig. 1 Plots of $R_1(\tau)$ against τ. The procedure used for computing $R_1(\tau)$ was: (1) a time series $\delta(\tau)$ of length 5,000 was generated from a model; (2) the data were normalized to produce a time series $\bar{\delta}(\tau)$ with maximum and minimum values 1 and 0 respectively; (3) three-dimensional normalized data states were sorted to determine pairs of data states which agreed to 10^{-3} in each component; (4) $R_1(\tau) = \log|\bar{\delta}(t_1+\tau) - \bar{\delta}(t_0+\tau)|$ was computed for six values of τ, beginning at $\tau = 0$ with the last coordinate of the matched data states. The five graphs were produced from time series generated by the following systems: *a*, $\delta(\tau) = \sin u(t)$, $u(t)$ the first component of $T^t(x, y)$, $T(x, y) = (2x + y, x + y) \bmod 1$; *b*, $\delta(t)$ is the first component of $H^t(x, y)$, $H(x, y) = (0.3y, 1 + x - 1.4y^2)$, the Henon map[17]; *c*, $\delta(t)$ is $\bar{h}^t(x)$, $\bar{h}$ is a gaussian random perturbation of the one-dimensional iteration $h(x) = 3.832x(1-x)$ (to prevent values occurring outside [0, 1], $\bar{h}(x)$ was set to $1 - y$ or $-y$ if the computed value y of $h(x)$ + random perturbation was >1 or <0); *d*, $\delta(t)$ is $\bar{h}^{3t}(x)$, $\bar{h}$ as in *c*; *e*, $\delta(t)$ is independent trials of a gaussian 'random' process constructed from a congruential pseudorandom number generator.

a strange attractor appear chaotic even though its evolution is determined completely by initial conditions. There is a sensitive dependence to initial conditions which prevents long-term prediction of the location of a trajectory within the attractor due to the uncertainty in our measurements of initial conditions. I interpret the Ruelle–Takens theory as asserting that aperiodic fluid flow is described by a strange attractor. This behaviour contrasts with randomness in the flow. Here randomness is defined as unpredictability in the short term evolution of a system. The present aim is to estimate the extent of randomness or noise in a system from the data which it produces.

In analysing a time series, I begin with the hypothesis that it can be described by evaluating a function along a trajectory in a strange attractor of a system with few degrees of freedom. This hypothesis implies that the trajectory will visit some regions of the state space repeatedly, returning many times to positions that are close to ones that it occupied previously. When this happens, the corresponding observations in the time series approximate each other. Indeed, entire sections of the time series approximate each other over time intervals for which the trajectories remain close. A second assumption about the function defining the time series allows this observation to be reversed.

Packard *et al.*[12,13] and Takens[14] have developed a procedure for recovering the location of a point in the state space from a section of the time series based on the Whitney embedding theorem[15]. Specifically, the trajectory with initial condition x is denoted by $\phi(x, t)$ and a time interval Δt selected. We then assume that the functions f_i defined by $f_i(x) = f(\phi(x, i\Delta t))$ are in a general position. The embedding theorem then implies that the mapping F defined by $F(x) = (f_0, f_1, \ldots, f_k)$ is an embedding of the state space into R^{k+1} if K is at least twice the dimension of the state space. We need only observe here that if $\phi(x, t)$ is a trajectory, then the observations $f(\phi(x, t + i\Delta t))$, $0 \leq i \leq n$, determine uniquely the location of $\phi(x, t)$ when n is large enough.

Sections of a discrete time series $\delta(t)$ are now used which approximate each other to assess the extent to which the data $\delta(t)$ could have been generated by a dynamical system with a low dimensional state space. An integer k is selected and a $(k+1)$-dimensional data state $\Delta(t)$ defined to be a $(k+1)$ vector $(\delta(t), \delta(t+1), \ldots, \delta(t+k))$. If k is sufficiently large and the data can be generated by a strange attractor, then $\Delta(t+1)$ is determined by $\Delta(t)$ by means of an unknown $(k+1)$ order (nonlinear) difference equation.

The practical problems here are that (1) no physical process is entirely free of randomness, and (2) any experiment gives us limited quantities of data. Nonetheless, the data states defined above can be used to estimate the randomness in a system. In two procedures used as an initial test for these methods, the data states of a time series are sorted to locate efficiently the pairs and triples of data states which are close to each other. Longer sections of the data which include these data states can then be examined.

The first procedure is based on the observation that the divergence of trajectories from one another in a strange attractor is approximately exponential, at a rate determined by the

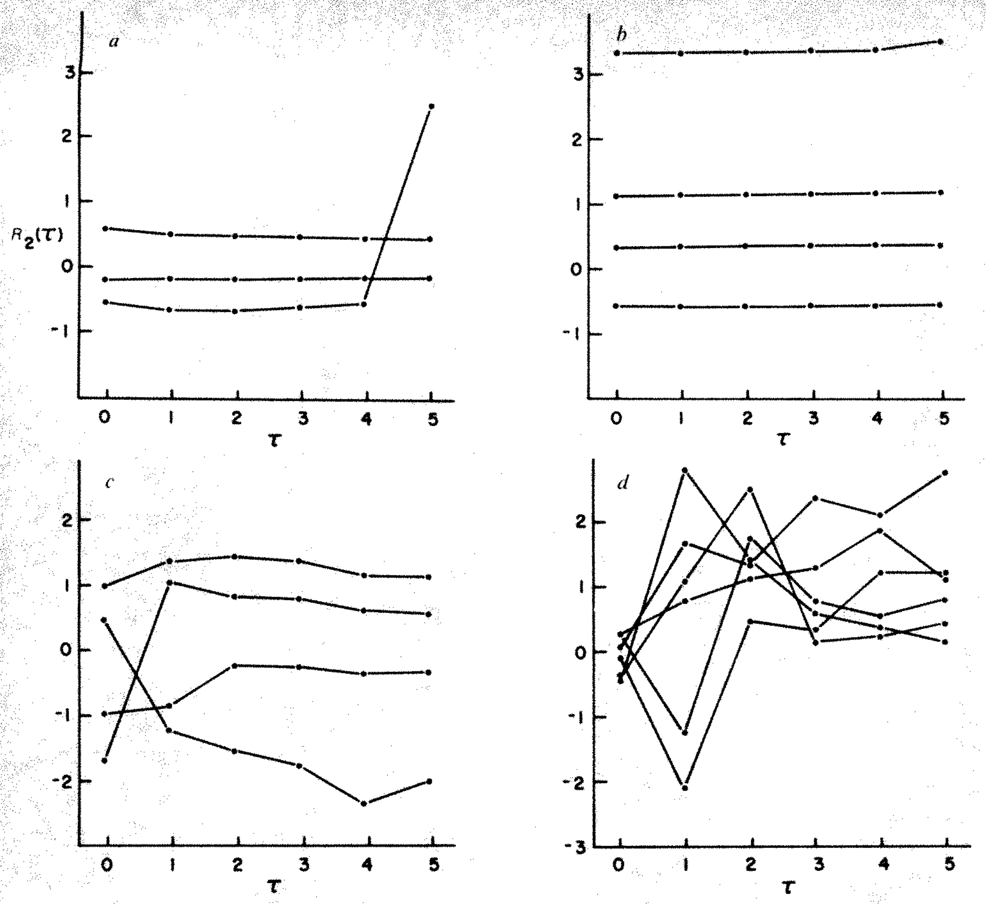

Fig. 2 Plots of $R_2(\tau)$ against τ for the same time series $\delta(t)$ used in Fig. 1*a–d*. To compute R_2 from $\delta(t)$, nearby triples of data states were located. With $\tau=0$ corresponding to the last component of the matched data states,

$$R_2(\tau)=\frac{\delta(t_2+\tau)-\delta(t_1+\tau)}{\delta(t_0+\tau)-\delta(t_1+\tau)}$$

was computed for $\tau=0,\ldots,5$.

largest Liapunov exponent of the trajectory. This suggests that the difference $R_1(\tau)=\log|\delta(t_1+\tau)-\delta(t_0+\tau)|$ of two sections of the time series $\delta(t)$ should be approximately linear in τ with slope which is generally independent of the sections of data chosen in a given region of the state space. Thus the first step is to measure $R_1(\tau)$ for sections of data which immediately follow pairs of nearby data states $\Delta(t_0)$ and $\Delta(t_1)$.

There is a limitation in using $R_1(\tau)$ due to the nonuniformity of the spreading of trajectories in different parts of a strange attractor and to the nonlinearity of the observing function f. The second procedure examined the statistics

$$R_2(\tau)=\frac{\delta(t_2+\tau)-\delta(t_1+\tau)}{\delta(t_0+\tau)-\delta(t_1+\tau)}$$

at times following the close approach of the corresponding triple of data states. In sections of a time series for which the strange attractor hypothesis indicates exponential divergence, $R_2(\tau)$ should be almost constant. In our present tests R_2 seems to be less susceptible to the nonlinearity of the observable and the nonuniformity of an attractor than R_1.

The statistics R_1 and R_2 are designed to examine more directly the extent of the randomness in a system than the procedures described by Takens[14] and Froehling *et al.*[12,13]. Takens partitions the space of k-dimensional data states into boxes of size ε. He uses the number $N(k,\varepsilon)$ of boxes populated for varying k and ε to estimate the topological entropy and capacity of a strange attractor. However, in a system with randomness, the noise can be expected to dominate the counts $N(k,\varepsilon)$ when ε is considerably smaller than the amplitude of the noise. This places limitations on the suitability of Takens' process for data with moderate amounts of noise. One might obtain an indication of the noise amplitude in a set of data if there is a pronounced plateau in $N(k,\varepsilon)$ with varying ε, but the issue of short term predictability is not addressed directly. Froehling *et al.*[12,13] use a method of local linear regression to fit the set of data states in a given region of the space of data states to a linear subspace. This procedure is complementary to the one described here and can be used to select an optimal value for the dimension of the data states which should be used when computing the statistics R_1 and R_2. The LLR method does not appear to be effective in assessing the issue of short term predictability.

The extreme examples which have been examined with these two procedures are a linear toral Anosov diffeomorphism[16] and independent trials of a gaussian random variable. The toral diffeomorphism is defined by $T(x,y)=(2x+y, x+y)$, where x and y are regarded as cyclic coordinates (mod 1). The whole two-dimensional torus is a strange attractor for T. The nonlinear function $f(x,y)=\sin x$ was used to generate time series $\delta(t)$ for this system. Examples have also been examined of the time series drawn from the x-coordinate of iterates of the Henon mapping[17] defined by $H(x,y)=(0.3y, 1+x-1.4y^2)$, and a random perturbation of a one-dimensional quadratic iteration $h(x)=3.832x(1-x)$. This perturbation was formed by adding to $h(x)$ a gaussian random variable constructed from a congruential pseudorandom number generator.

Figure 1 shows the results obtained from applying the first procedure to time series of 5,000 observations drawn from each of the examples. Nearby three-dimensional data states have been located, and then $R_1(\tau)$ has been plotted for the last components of the nearby data states and for the five observations immediately following these. The results clearly separate the deterministic systems from the pseudorandom gaussian process. The nonuniformity of the expansion in the Henon mapping is reflected in the smaller values of R_1 at the third observation following the matched data states compared to the second. For the one-dimensional iteration, the deterministic features dominate the randomness at this scale. To show the randomness more clearly, Fig. 1*d* shows the results of selecting every third data point (there is a stable period 3 cycle in the deterministic map) and then working on a finer scale of resolution. The randomness in the data shows clearly in Fig. 1*d*. Note also in Fig. 1*d* and *e* the large magnitude of the uncertainty in the knowledge of the next observation associated with our current knowledge of the data state.

Figure 2 shows R_2 statistics for the same time series. The gaussian process produced only one triple which was a close match, and this was very erratic. Only graphs with moderate values of the R_2 statistic are shown. The R_2 statistic works strikingly well for the Anosov and Henon mappings, while the one-dimensional iteration gives an indication of a small amount of randomness. Looking at the finer scale of resolution for the third iterate of this process, the randomness is once again dominant.

The results of these initial test on models of strange attractors and stochastic systems are promising. The differences between time series generated by strange attractors and those generated by systems with some randomness are apparent. There are three specific indications of determinism versus randomness in the tests we have performed with these model data:

(1) If $\tau = 0$ denotes the time of the last observations used in matching nearby data states, then a large value of $R_1(1) - R_1(0)$ shows that one state has exceeded the resolution at which one step prediction is possible.

(2) Approximately constant differences in the values of R_1 computed from different trajectories demonstrate a consistent pattern of separation of trajectories like that present in strange attractors.

(3) Approximately constant values of $R_2(\tau)$ compared with τ give an indication similar to (2) of the orderly separation of trajectories found in strange attractors.

I suggest that statistics such as R_1 and R_2 may help resolve questions about whether the irregularities of time series drawn from experimental observations are due to effects which can be described by deterministic systems with few degrees of freedom. The problems discussed above are related to questions about entropy and fractal dimension of data[14], but the methods reported here address the question of randomness as the cause of irregularity more directly.

Natural production of tritium in permeable rocks

J. N. Andrews

School of Chemistry, University of Bath, Claverton Down,
Bath BA2 7AY, UK

R. L. F. Kay

Institute of Geological Sciences, Environmental Protection Unit,
Building 151, Harwell Laboratory, Didcot, Oxon OX11 0RA, UK

Natural tritium production by the reaction, ${}^6_3\mathrm{Li}(n,\alpha){}^3_1\mathrm{H}$, may in some circumstances lead to ${}^3\mathrm{H}$ contents in the fracture fluids of a granite, which are significantly above the present natural ${}^3\mathrm{H}$ content (0.5 tritium units, TU) of pre-bomb precipitation. We show here that the principal factors which determine the ${}^3\mathrm{H}$ content of the fracture fluids are the U, Th, Li and B contents of the rock and its matrix porosity. Granites with high U, Th and Li contents; low B content and a low matrix porosity may have a naturally maintained ${}^3\mathrm{H}$ content of up to about 2.5 TU in water within the matrix. This has important implications for the interpretation of groundwater flow patterns from their ${}^3\mathrm{H}$ contents. Whereas it has generally been assumed that groundwaters with ${}^3\mathrm{H}$ contents greater than 0.5 TU have a proportion of post-1954 recharge present, this may not always be a valid conclusion.

Precipitation after 1954 contained ^{3}H which was produced by the thermonuclear weapon testing in the atmosphere. The ^{3}H content of rainfall in the UK has declined from a maximum of ~2,000 TU in 1963 to about 60 TU in 1975[1]. The pre-1954 ^{3}H content (due to cosmic ray production) of precipitation on the western coast of Europe was ~2.5 TU (ref. 2) and a groundwater which was recharged in 1953 with this ^{3}H content would at present (1982) contain only a residual 0.5 TU because of ^{3}H decay (half life, 12.3 yr). A groundwater with the natural ^{3}H input (2.5 TU) would need to be ~60-yr old to reduce its ^{3}H content to 0.1 TU by decay. This is about the analytical limit[3] for determining ^{3}H in water.

A groundwater with a ^{3}H content ≥ 0.1 TU is therefore generally considered to be younger than 60 yr and, especially if the ^{3}H content exceeds a few TU, to contain a proportion of post-1954 precipitation. Here, we consider whether or not it is possible that groundwaters older than 60 yr could contain levels of ${}^3\mathrm{H} > 0.1$ TU due to *in situ* production of ^{3}H. Such production is most likely for groundwaters from granites for which lithium and radioelement contents are comparatively high.

The only nuclear reaction which can produce significant ^{3}H natural activity by in-ground production is the neutron-induced reaction:

$$ {}^6_3\mathrm{Li}(n,\alpha){}^3_1\mathrm{H} \qquad (1)$$

The thermal neutron cross-section for this reaction[4] is large and neutrons are produced in rocks by both spontaneous fission of uranium and by (α, n) reactions on the major matrix elements; Si, O, Al, Mg. The activity of ^{3}H produced at a constant rate P by neutron irradiation of lithium for time t is given by:

$$\left(\frac{dN_r}{dt}\right)_t = \lambda (N_r)_t = P(1-e^{-\lambda t}) \qquad (2)$$

where $(N_r)_t$ is the number of ^{3}H atoms present after time t and λ is the decay constant for ^{3}H, from which

$$(N_r)_t = \frac{P}{\lambda}(1-e^{-\lambda t}) \qquad (3)$$

and

$$\lim_{t\to\infty} (N_r)_t = \frac{P}{\lambda} \qquad (4)$$

P may be estimated in a manner similar to that used by Zito *et al.*[5] to estimate in-ground ^{14}C production. The chance, F, of neutron absorption by Li relative to absorption by other neutron-absorbing elements is given by:

$$F = \sigma_{\mathrm{Li}} N_{\mathrm{Li}} \Big/ \sum_1^{92} \sigma_i N_i = \sigma_{\mathrm{Li}} N_{\mathrm{Li}} / C_t \qquad (5)$$

where σ_i, N_i are the total neutron absorption cross-sections and abundances for all elements in the matrix; σ_{Li} is the cross-section for reaction (1) and N_{Li} is the abundance of Li in the matrix. The $\sigma_i N_i$ summation, C_t, may be regarded as the total neutron capture probability for the rock matrix and the terms

0028–0836/82/29036 —03$01.00

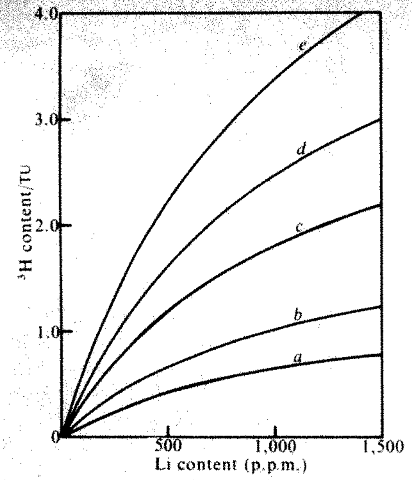

Fig. 1 Variation of the ^{3}H content of water in a granite with the Li, U and Th contents. A boron content of 15 μg per g (average granite, ref. 6) and an equivalent total porosity (see text) of 1% were assumed. *a*, 3.5 p.p.m. U+18 p.p.m. Th; *b*, 10 p.p.m. U+15 p.p.m. Th; *c*, 20 p.p.m. U+20 p.p.m. Th; *d*, 30 p.p.m. U+20 p.p.m. Th; *e*, 40 p.p.m. U+30 p.p.m. Th.

of this summation for various rocks are listed in Table 1. The Li-content of the rock matrix directly influences the ^{3}H production rate and B, because of its strong influence on the total capture probability, needs to be further considered. This may be facilitated by substituting for C_t in equation (5) as follows:

$$C_t = C + \sigma_{\text{Li}} N_{\text{Li}} + \sigma_{\text{B}} N_{\text{B}} \qquad (6)$$

where C is the total absorption probability excluding the contributions of Li and B. For a granite matrix, the fraction F, of thermal neutrons captured by Li may be shown to be:

$$F = [\text{Li}]/\{1.057\times10^{-7} + [\text{Li}] + 6.827[\text{B}]\} \qquad (7)$$

where [Li] and [B] are the Li and B contents of the rock in μg per g. This equation was derived for the elemental composition of average granite[6] using cross-sections for thermal neutron absorption. Only thermal neutron absorption has been considered as the cross-sections for fast neutron absorption reactions are generally very much smaller than those for thermal neutron reactions and the high abundance of light elements (O, Si) in the matrix ensures that neutrons are thermalized by scattering processes. The ^{3}H production rate, P, is given by:

$$P = Fn \quad \text{atoms s}^{-1}\,\text{cm}^{-3} \qquad (8)$$

where n = neutron production in the rock, neutrons $\text{s}^{-1}\,\text{cm}^{-3}$. The neutron production in granites has been estimated by Feige *et al.*[7] (Table 2).

Following neutron-induced fission of ^{6}Li, the ^{3}H nuclei formed capture electrons to form ^{3}H atoms which diffuse through the rock matrix much more readily than molecular hydrogen. Their ultimate fate is to combine to form $^3H_2$ or to exchange with the H atoms of water molecules to form ^{3}HHO. The latter is much more probable than direct combination in a matrix which contains aqueous fluids as the diffusing ^{3}H atoms are likely to encounter water molecules before they meet other ^{3}H atoms. Exchange of the diffusing ^{3}H atoms with structurally bound water or hydroxyl groups in the rock matrix is also likely to occur. The total water content of the matrix, that is, structurally bound water and pore- or fracture-contained water, may be combined to obtain an equivalent total porosity, ϕ, for the rock. The ^{3}H atoms are trapped on a random basis by the total water in the matrix and its specific activity in structurally bound and pore water is therefore identical with that in the fracture fluids from which samples are generally drawn.

The ^{3}H content of the fluid is given by the equation:

$$^3\text{H-content(TU)} = \frac{P}{\lambda\ \phi} \frac{18\times10^{18}}{\times 2\times6.02\times10^{23}} \qquad (9)$$

where λ (0.0559 yr^{-1}) is the decay constant of ^{3}H and P is the ^{3}H production rate (atoms yr^{-1}); as there are $2\times6.02\times10^{23}$ H atoms in 1 mole (18g) of water and 1 TU is defined as 1 ^{3}H atom in 10^{18} H atoms. The ^{3}H content is inversely proportional to the equivalent total porosity and will become most significant for rocks with both low porosity and only small amounts of structurally bound water. Recent measurements on various granites[8,9] suggest that the minimum porosity is in the range 0.3–0.5%. The amount of structurally bound water is also about 0.5% for unaltered granites[9]. The minimum equivalent total porosity for granite is therefore ~1% and *in situ* ^{3}H contents were calculated for this porosity. Figure 1 shows the variation of ^{3}H content with the Li and radioelement contents for a granite of average B content (15 μg per g). At high Li and radioelement contents, *in situ* ^{3}H production could lead to ^{3}H contents in the fracture fluids which exceed the maximum possible residual cosmogenic ^{3}H from recharge just before 1954

(0.5 TU). The effect of increased B contents is demonstrated by Table 3. In general, a 10-fold increase in B content results in a 3- to 5-fold reduction in the amount of *in situ* produced ^3H in the fracture fluids. Variation of the Gd content of the matrix would also significantly affect ^3H production.

The Carnmenellis granite, one of the major outcrops of the granite batholith of South West England[10], is known to have high radioelement and Li contents. High salinity groundwaters occur in tin mines at depths of up to 690 m, and these have been shown to result from alteration reactions of the granites with meteoric waters[11]. These waters had apparently constant ^3H contents of 6 ± 2 TU over a range of salinities and this could be a consequence of either *in situ* ^3H production or variations in the extent to which alteration reactions have proceeded.

Lithium is generally present in the biotite[12] and an average whole-rock Li content for the Carnmenellis granite is 278 μg per g, compared with an average Li content of 340 μg per g for the similar, poorly megacrystic, Dartmoor granite[13]. Higher average Li contents (~1,100 μg per g) are present in the St Austell granite[12].

The available data for the Carnmenellis granite suggest that its B content is of the order 250 μg per g, compared with 15 μg per g for average granite. Outcrop samples of the Bodmin granite have an average B content of 270 μg per g whilst the two available analyses (J. R. Hawkes personal communication) of the Carnmenellis granite are 85 and 230 μg per g respectively. Tourmaline is the principal B-bearing mineral and is present in both primary and secondary forms[10]. The variation of B content with depth in the granite is not known but it is likely that secondary tourmalinization is greater towards the granite margins. The B content at depth is therefore unlikely to be greater than that at outcrop. The Gd contents of the Cornish granites[14] are similar to those for average granite.

The dependence of ^3H production in the Carnmenellis granite on Li and B contents is indicated in Table 3. It is evident that for the probable geochemical conditions in this granite (250–500 μg per g of Li; 250 μg per g of B), the *in situ* ^3H production cannot supply more than 0.5 TU to the fracture fluids. Higher Li contents occur in the nearby St Austell granite for which the B content is lower (<50 μg per g), so that tritium in excess of 1 TU could be present in fracture fluids as a result of *in situ* production. It is, however, concluded that the 6 TU observed in the deep groundwaters from the Carnmenellis granite must be principally due to the presence of meteoric water of post-1954 origin. In the most favourable case for ^3H production, a granite with a high Li content and an average B content, the consequent fracture fluid ^3H content is unlikely to exceed 1 TU in most cases, or up to 2.5 TU for highly uraniferous granite.

Table 3 ^3H-content of fracture fluids resulting from *in situ* ^3H-production, for various Li and B contents in the Carnmenellis granite*

Role of Mn(IV) oxide in abiotic formation of humic substances in the environment

H. Shindo* & P. M. Huang

Saskatchewan Institute of Pedology, University of Saskatchewan,
Saskatoon, Saskatchewan, Canada S7N 0W0

The oxidative polymerization of polyphenols in soils is regarded as one of the main processes in the formation of humic substances[1–7]. The polymerization causes the darkening of the colour of polyphenols—the 'browning phenomenon'—which can be accelerated non-enzymatically as well as enzymatically[7–15]. However, the relative effectiveness of various inorganic components, especially noncrystalline to poorly crystalline Fe, Al, Mn and Si oxides commonly occurring in soils[16–19], in affecting the browning of polyphenols is still obscure. The elucidation of the relative effectiveness of these oxides is of importance in understanding their roles in the formation of humic substances in the environment. We report here that Mn(IV) oxide is a very effective oxidant with respect to the abiotic browning of hydroquinone solution over the *p*H range (4–8) common in soil. On the other hand, the accelerating effect of Fe oxide on the browning is extremely small. The promoting effects of Al and Si oxides were not observed in the conditions studied. The results obtained in the present study indicate that Mn(IV) oxides deserve close attention in the abiotic formation of humic substances in the environment.

* The experimental procedures were as stated in Fig. 1.

† The supernatant is visibly colourless and its absorbance is <0.01.

Noncrystalline or poorly crystalline oxides of manganese (birnessite, δ-MnO_2), iron, aluminium and silicon were prepared and used in this study as they commonly occur in soils[16–19]. Hydroquinone was used as the phenolic compound in this study, because benzoquinone derivatives are known to be parts of the chemical structure of humic acid[2,3,5,6], and the use of catechol derivatives which rapidly form coloured chelate complexes with iron[20] is inadequate for this study.

Figure 1 shows the absorption spectra of several browning solutions in the visible region at the end of the reaction period of 24 h. The colours of the solutions were light reddish brown to dark brown, and differed from the colour (yellow) of *p*-benzoquinone which is an oxidized monomeric product of hydroquinone. The shapes of their spectra varied with the reaction conditions, indicating that substances with varying degrees of polymerization were formed. Their absorbances in the visible region were distinct from each other. The degree of the browning of hydroquinone solution as influenced by the various oxides can be compared by using light absorption at given wavelengths. The degree of humification of humic acid is commonly determined using light absorbances at 400 and 600 nm (ref. 9). Therefore, in this study, the absorbances at 400 and 600 nm were used to determine the effects of the oxides on the browning.

Table 1 shows the effects of Mn, Fe, Al, and Si oxides on the browning of hydroquinone solution at different *p*H values at the end of the reaction period of 24 h. The control solution without the oxides became coloured only when the initial *p*H of the solution was 7.0 or higher. The degree of the browning at *p*H 7.8 was higher than that at *p*H 7.0, indicating that oxidative polymerization was promoted at the higher *p*H. The addition of Mn oxide greatly accelerated the browning over the *p*H range (4.0–7.8). The degree of the browning in the Mn oxide system was influenced by the *p*H values. In the case of *p*H 5.0, the degree of the browning was much lower than that at other *p*H values. In both solutions of *p*H 4.0 and 5.0, the

Table 2 Effects of antiseptic and inoculum on the browning of hydroquinone solution both in the absence and presence of birnessite at the end of the reaction period of 24 h

* 20 mg of Mn oxide (birnessite)[21] was suspended in 20 ml of 0.1 M sodium acetate solution at *p*H 6.0 containing 10 μmol ml^{-1} hydroquinone; in certain cases, 2 ml of water, 2 ml of 1% $HgCl_2$, 1 ml of toluene or 2 ml of inoculum was added. The subsequent procedures are as stated in Fig. 1.

† Filtrate was obtained from the soil water suspension (soil:water ratio = 1:10). The fresh soil sample was taken from the Ap horizon of the Unity Orthic soil in Wilkie, Saskatchewan, Canada.

‡ The growth of microorganisms in the solution at the end of the reaction period of 24 h was examined using agar plates which contained nutrient broth and agar[24].

§ ND, no colonies were observed on the plates even after 4 days.

‖ The supernatant is visibly colourless and its absorbance is <0.01.

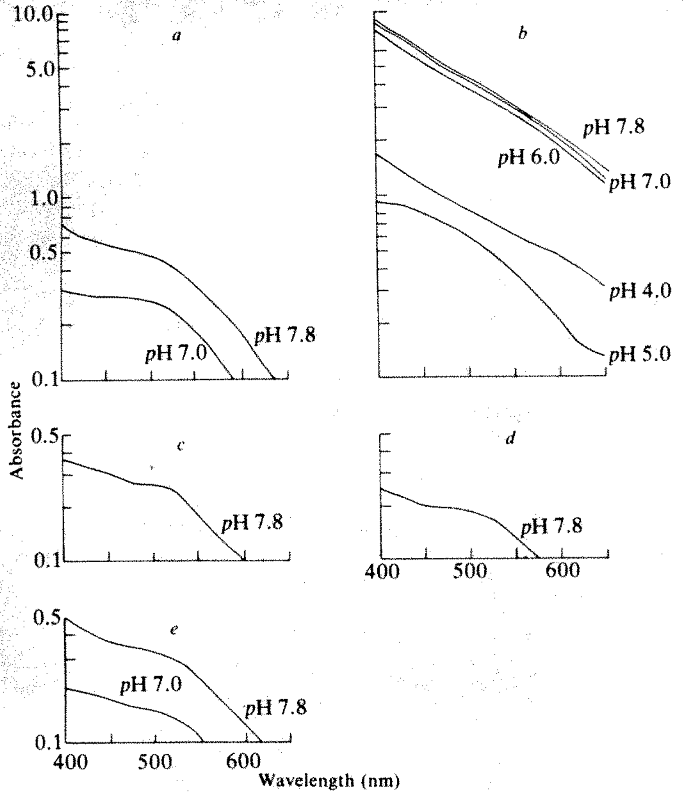

Fig. 1 The absorption spectra of several browning solutions in the visible region at the end of the reaction period of 24 h. *a*, Control (hydroquinone); *b*, Mn system; *c*, Fe system; *d*, Al system; *e*, Si system. pH means initial pH of the hydroquinone solution used. In systems *b* to *e* the Mn oxide (birnessite)[21], Fe (ref. 22), Al (ref. 22), and Si (ref. 23) oxides were prepared. Twenty mg of each oxide was suspended in 20 ml of 0.1 M sodium acetate solution at different pH values containing $10\ \mu mol\ ml^{-1}$ hydroquinone. The flasks (125 ml) containing the suspensions were placed in an oscillating shaker in a water bath at 25 °C for 24 h. After the reaction period, the suspension was centrifuged at 38,000*g* for 20 min. The absorbance of the supernatant was measured with a spectrophotometer directly or after dilution; the resulting absorbances were scaled by the dilution factor. The sodium acetate solution which did not contain hydroquinone was used as reference.

Mn oxide added was dissolved at the end of the reaction period of 24 h. In the solution of pH 5.0, a very broad absorption band ranging from 400 to 600 nm was observed; this is different from the other Mn systems (Fig. 1*b*). Therefore, the low degree of the browning at pH 5.0 may be attributed to the formation of a stable complex which does not polymerize further. In the cases of pH 6.0 or higher, the degree of the browning was much higher than that at pH 4.0 or 5.0. This result cannot be explained by the *Eh* values of the system, because *Eh* decreased with increasing pH. In the Mn oxide systems to which were added solutions of initial pH values of 6.0, 7.0 and 7.8, the final pH values ranged from 7.5 to 7.7. On the other hand, final pH values in the control systems ranged from 6.0 to 6.9. Therefore, the high degree of the browning in the Mn oxide systems at the initial pH values of 6.0 or higher is attributed to the following processes: (1) the Mn oxide acts as a Lewis acid which accepts electrons from hydroquinone leading to its oxidative polymerization and (2) the acceleration of oxidative polymerization which is driven by an increase of pH which is in turn caused by the reduction of Mn oxide.

The absorption spectra of the browning solutions in the Mn systems at pH 4.0, 6.0, 7.0 and 7.8 (Fig. 1*b*) were similar to those of humic acids[9]. Their $\Delta\log K$, namely, the logarithm of the ratio of the absorbance at 400 nm to that at 600 nm (ref. 9), ranged from 0.55 to 0.62. This indicates that Mn oxides are capable of accelerating the conversion of phenolic compounds such as hydroquinone to humic acid-like polymers with a relatively high degree of humification.

The promoting effect of Fe oxide on the browning was observed only in acidic conditions, and the effect was higher at pH 4.0 than at pH 5.0 (Table 1). The accelerating effects of Al and Si oxides on the browning were not observed at all the pH conditions studied.

The control solution became coloured when the solution was adjusted to pH 7.0 or 7.8. In the presence of Fe, Al and Si oxides, a decrease in the degree of the browning was observed. This decrease is attributed to the adsorption of the browning substances by the oxides.

To determine whether microorganisms influence the browning of hydroquinone solution in the conditions studied, antiseptic or inoculum was added to the system. The browning of hydroquinone solution was then studied. As shown in Table 2, the hydroquinone solution in the absence of Mn oxide was colourless both in the absence and presence of toluene or inoculum. The degree of the browning in the Mn oxide system was not influenced by the presence of either toluene or inoculum. $HgCl_2$ slightly accelerated the browning of hydroquinone solution without Mn oxide, indicating that $HgCl_2$ has a weak power in causing the browning. The presence of Hg(II) in the Mn oxide system slightly suppressed the browning. $HgCl_2$ is a considerably weaker oxidant than MnO_2 (Table 2). Therefore, the influence of $HgCl_2$ on the browning of hydroquinone solution by MnO_2 may be attributed to the blocking of a portion of Lewis acid sites on the surfaces of MnO_2 by Hg(II). Agar plates, inoculated with the browning solution, did not show any growth of microorganisms (Table 2). Therefore, the results clearly show that the browning of hydroquinone solution in the conditions studied occurs abiotically.

Our data reveal that Mn(IV) oxide is a very effective oxidant compared with Fe, Al and Si oxides in the abiotic browning of hydroquinone. This finding indicates that Mn(IV) oxide may have an important role in the formation of humic substances in the environment.

This study was supported by a grant from the Natural Sciences and Engineering Research Council of Canada. We thank Dr J. J. Germida in our Institute for help with the microbiological aspects of the experiment.

Is the CH_4, H_2 and CO venting from submarine hydrothermal systems produced by thermophilic bacteria?

John A. Baross, Marvin D. Lilley
& Louis I. Gordon

School of Oceanography, Oregon State University, Corvallis,
Oregon 97331, USA

Submarine hydrothermal vents are a major source of methane to the oceans[1,2]. The methane, as well as H_2 and CO, are generally believed to result from degassing of the mantle or from abiogenic water–rock reactions[1], a conclusion supported by direct correlations between ^3He and CH_4, and generally between CH_4, H_2 and CO and dissolved silicate in hydrothermal waters[2,3]. An alternative source for these gases might be microbiological. This would imply that active bacterial communities exist in deep-sea hot water environments, some of which have temperatures exceeding 100 °C; this inference is without precedent. We have now found that the super-heated waters emanating from sulphide chimneys at 21 °N along the East Pacific Rise and samples from the sulphide chimneys themselves harbour complex communities of bacteria capable of growing with generation times of 37–65 min, producing CH_4, CO, H_2 and traces of N_2O in media containing $S_2O_3^{2-}$, Mn^{2+} and Fe^{2+} as energy sources, and oxidizing CH_4, at 100±2 °C at 1 atm. These microbial communities consist of three to five morphologically distinct types and include both oxidative and anaerobic species. These mixed cultures will not grow at temperatures below 70–75 °C. Even though some of the communities originated from water of temperatures >300 °C, it is not known if they can grow and produce CH_4, CO and H_2 in super-heated waters kept liquid due to hydrostatic pressure. The discovery of these obligately thermophilic, gas-producing and consuming bacterial communities associated with submarine volcanic environments has interesting and important implications for prokaryotic evolution, marine geochemistry, industrial microbiology and exobiology.

Submarine hydrothermal systems located along tectonic rifts and ridges off the Galapagos Islands and along the East Pacific Rise[4–6] and the Gorda Ridge have been studied and sampled since 1977. Two groups of vents have been described: (1) cracks and small fissures which emit warm water (5–22 °C) at a flow rate of $\sim 2\,cm\,s^{-1}$ and (2) spectacular 3–10-m high conical sulphide mounds (chimneys) out of which spout super-heated waters with temperatures as high as 380±30 °C and flow rates of metres per second (ref. 5). At the depth of these hydrothermal systems (2,500–2,650 m) seawater can remain liquid at temperatures up to ~460 °C due to the effect of hydrostatic pressure[7]. Sulphide chimneys are found at 21° N along the East Pacific Rise, and the warm water vents are found at both the Galapagos Rift and at 21° N. Associated with each of these hydrothermal environments are extensive and diverse groups of animals which are now known to derive their energy from chemosynthetic bacteria[8,9]. These bacteria, which are found in large numbers in warm vent waters[4,9], on animal and rock surfaces[10,11], and as endosymbionts associated with specific vent animals[12], utilize S, metals and possibly organic gases and H_2 as energy sources. Bacteria had previously not been thought to exist in the super-heated waters associated with sulphide chimneys.

During October and November 1979, samples of hot vent water, sulphide chimney sections and associated fauna were obtained from the East Pacific Rise at 21° N using the manned submersible, *Alvin*. The present report is based on microbial cultures obtained from eight hot water samples from black and white smoking chimneys and one chimney wall sample. Initial chemical, physical and microbiological analyses of these waters were made on board the R/V *Gillis* shortly after the samples surfaced.

In general, the concentrations of the biologically important chemical constituents, H_2S, Mn and Fe, were high in all samples. The concentration of each chemical species was dependent on the degree of mixing with ambient seawater (Table 1). Degree of mixing is indicated by the difference in the water temperatures, both as measured with a temperature probe attached to the *Alvin* and as calculated from Mg numbers (see corrected temperature measurements, Table 1). Also, the presence of anaerobic and aerobic bacteria capable of growing at 25 °C in some of the samples indicate mixing of the sample with bacteria from ambient or warm vent water. This is particularly apparent

Table 1 Chemical and microbiological characteristics of hot water venting from sulphide chimneys at 21° N along the East Pacific Rise

Sample designation	Temperature (°C)		pH	Concentration of biologically important constituents (μM)				Total nos of bacteria			Presence of thermophiles
									Viable counts at 25 °C (ml^{-1})		
	Probe	Corrected		H_2S	Mn	Fe	Si	Direct counts (ml^{-1})	Aerobic	Anaerobic	
978 5/6	220	195	5.12	7.5	1,055	153	11,700	1.4×10^4	<1	80	+
978 7/8	120	22	6.04	600	120	20	1,300	7.4×10^5	<1	310	+

982 7/8	290	306	4.24	4,300	800	—	18,320	4.7×10^5	<1	<1	+
978(Niskin)*	3	3	Sample not analysed chemically					8.6×10^5	5.3×10^3	<1	–

All water samples were obtained with 750 ml gold-plated stainless steel and brass (one valve) samplers (provided by Sandia Laboratories, New Mexico) using the submergence research vehicle *Alvin* in October 1979. Subsamples were taken into sterile 20–150-ml bottles. Corrected temperature measurements were calculated from the relationship: $T = 0.00667$ (°C μmol^{-1}) (Mg) where Mg = Mg ambient − Mg measured; T = sample temperature. Mg data were provided by J. Edmond. All chemical measurements and pH were from John Edmonds (unpublished). Total direct bacterial counts were measured by epifluorescent microscopy using the procedures of Zimmerman and Meyer-Reil[21]. Water samples were immediately fixed on shipboard with 2% glutaraldehyde (Tousimis, electron microscopy grade) and maintained at 1 °C until counted back in the laboratory; total aerobic viable bacteria were enumerated using a basal salt medium (MS) which contained: NaCl, 26 g; KCl, 0.8 g; $MgCl_2 \cdot 6H_2O$, 5.6 g; $MgSO_4 \cdot 7H_2O$, 7.6 g; $CaCl_2$, 0.1 g in 1 l twice distilled water; MS was supplemented with $Na_2S_2O_3 \cdot 5H_2O$, 0.5%; $FeSO_4 \cdot 7H_2O$, 0.02%; $MnSO_4 \cdot H_2O$, 0.08%; $Na_2MoO_4 \cdot 2H_2O$, 0.001%; Na_2HPO_4, 0.9%; KH_2PO_4, 0.15%; $NaNO_3$, 0.1% trace element mixture according to Rippka, *et al.*[22]; medium adjusted to pH 7.5. Total anaerobic viable bacteria were enumerated using MS supplemented with 0.25% sodium formate, 0.1% $NaNO_3$, trace element mixture and phosphate buffer (above) at pH 7.5 and incubated in anaerobic jars in an atmosphere of H_2 and CO_2 using BBL Gas Pax disposable gas generator envelopes. Bacto purified agar (Difco) was dialysed in twice distilled water to remove soluble organic compounds and $12\,g\,l^{-1}$ was used. Water samples were enumerated using the spread plate technique for dilutions of 0.1, 0.01 and 0.001 ml whereas 1-, 5- or 10-ml samples were concentrated using 0.22-μm Millipore type GS membrane filter. The filters were then placed on the surface of the agar plates. The presence of thermophiles was detected using enrichment medium containing MS supplemented as described above for aerobic plating medium. Duplicate enrichments were adjusted to pH 5 and 7.5. A dilute heterotrophic medium 1/10 strength Lib-X (ref. 23) was also used. Glass screw-cap culture tubes (1.8 × 12 cm) containing 10 ml of the enrichment media were inoculated with 1–2 ml of the water sample. The inoculated samples were then placed in a boiling water bath for 1 h to minimize contamination and then incubated at 86 °C on a generator in the engine room of the R/V *Gillis*. All of the inorganic media enrichments at both pH 5 and 7.5 showed positive growth within 4 days. No growth was detected in the heterotrophic medium after 10 days.

* Sterile Niskin bag sample used to collect water from sites located adjacent to vents.

Table 2 Rate of H_2, CH_4 and CO production by 21° N hot water and sulphide-chimney associated bacterial communities at 100 ± 2 °C

				Gas production			
Sample	Inoculum size (per 30 ml)	Medium Type	pH	nmol per ml per h H_2	nmol per ml per h CH_4	nmol per ml^{-1} per 9 h CO	Presence of N_2O (nmol ml^{-1})
978 5/6 (water)	1.3×10^6	A(S–NH_4^+)	7	102	42	10	0.15 at 36 h
			5	71	39	9	ND
		C(formate)	7	31	27	11	0.12 at 36 h
		D(no energy source)	7	0.3	0.3	0.6	ND
		A(killed cells)*		ND	ND	ND	ND
982 7/8 (water)	3.0×10^5	A	7	54	22	14	Trace‡
		C	7	(110)†	(46)†	(22)†	Trace‡
		D	7	0.2	ND	ND	ND
		A(killed cells)		ND	ND	ND	ND
3140 (sulphide chimney rock)	6.1×10^5	B(S–NO_3^-)	7	24	24	7.5	Trace†
			5	23	22	10	ND
		C	7	26	25	10	1.3 at 36 h
		D	7	0.3	ND	ND	ND
		A(killed cells)		ND	ND	ND	ND

Inoculum size was determined using epifluorescent microscopy. All media were made with MS (see Table 1 legend) supplemented with trace element mix (Table 1) and buffered with 1.0 g l^{-1} HEPES (Sigma). Medium A contained 0.02% $FeSO_4\cdot7H_2O$; 0.06% $MnSO_4\cdot H_2O$; 0.002% $Na_2MoO_4\cdot2H_2O$; 0.02% $(NH_4)_2SO_4$; 0.2% $Na_2S_2O_3\cdot5H_2O$; 0.03% Na_2HPO_4; 0.05% $NaHCO_3$. Medium B is the same as medium A except 0.02% KNO_3 was used in place of $(NH_4)_2SO_4$ as a nitrogen source. Medium C contained 0.02% $FeSO_4\cdot7H_2O$; 0.06% $MnSO_4\cdot H_2O$; 0.002% $Na_2MoO_4\cdot2H_2O$; 0.02% $(NH_4)_2SO_4$; 0.02% sodium formate; 0.03% Na_2HPO_4. Medium D contained MS plus HEPES buffer and 0.03% Na_2HPO_4 and was used as a non-energy source medium. This medium was inoculated as described for other reactions. Cultures were inoculated into 60-ml serum bottles containing 30 ml medium. The serum bottles were capped with Teflon caps. All media were equilibrated at 98–100 °C before inoculation and capping. No gases were detected in any of the uninoculated medium controls. All gases were detected by gas chromatography using a modification of the procedure described by Swinnerton and Linnenbom[24] with a custom-built gas chromatograph equipped with helium ionization, flame ionization and electron capture detectors[25]. In all cases most of the H_2 and CH_4 was produced by these cultures within 3 h of inoculation. The levels of CO continued to increase over a period of 8–12 h. The rate of gas formation was calculated based on three measurements made at 45 min, 2 h and 3 h for H_2 and CH_4, and at 45 min, 3 h and 9 h for CO. ND, not detected.

* Inoculum was exposed to 5% neutralized formalin for 24 h at 15 °C. The cells were then centrifuged at 12,000g for 10 min in a Sorvall RC-2B, resuspended in medium A and diluted to 10^6 cells per ml after counting by epifluorescent microscopy.

† In these samples only one gas sample was measured after 30 h incubation. Based on other experimental results (see above) these concentrations of gases were probably reached within 3 h.

‡ Trace levels of N_2O were <0.1 nmol ml^{-1} but >0.025 nmol ml^{-1}.

in samples 979 11/12 and 979 1/2. These samples also showed the greatest degree of mixing based on the Mg temperature calculations. In all samples, except the ambient Niskin bag sample (978), bacteria capable of growing at 86 °C were detected by enrichment in media composed of inorganic energy sources at either pH 5 or 7, but not in a dilute heterotrophic medium. The hottest water sample (982 7/8), which came from a black smoker, had the highest concentration of H_2S, Mn and Si and the lowest pH. In contrast, the other hot sample (978 5/6), which originated from a white smoker, had considerably lower levels of H_2S. High concentrations of H_2, CH_4 and CO were detected in both these samples. Also, in samples 979 3/4 and 982 7/8 the concentrations of CH_4 and H_2 exceeded 20 and 200 μM, respectively (M.D.L. and L.I.G., unpublished). The mixed communities of thermophilic bacteria have been kept intact by incubating at 85 °C with the transfer of 50 ml of culture into 450 ml medium at 6–8-week intervals. The experimental results reported here used these cultured communities.

The mixed cultures of thermophilic bacteria from these hot waters grew slowly at 80–86 °C and there was no evidence of gas production. When the cultured bacterial communities were transferred to fresh medium and incubated at 100 ± 2 °C in a water bath using a high boiling commercial coolant, rapid growth and active gas ebullition were observed. Table 2 shows the specific gases synthesized by the cultures and their rate of formation at 100 ± 2 °C. The rapid production of CH_4 by these communities was unexpected because no precautions had been taken to maintain anaerobic conditions with the initial water samples or with subsequent cultures. The gases were formed at both pH 5 and 7 in inorganic media and in a formate medium. In contrast to the H_2 and CH_4, which were at detectable levels within minutes after the samples were prepared, CO and N_2O required 9–24 h of incubation to reach measurable concentrations. The sulphide chimney sample also harboured a thermophilic microflora capable of producing the same suite of gases as the hot water cultures. This suggests either that there is a resident population of these organisms associated with sulphide chimneys which could be washed off into the venting fluid, or that these sites are contaminated with hot water bacteria. The temperatures of the outer surfaces of the chimneys are not known, but observable schlieren indicate that they are considerably warmer than the ambient seawater (J.A.B. and L.I.G., unpublished observation).

The thermophilic communities investigated are composed of anaerobic and aerobic bacteria including methanogens and methylotrophs. Table 3 shows the rate of CH_4 oxidation by these cultures. Neither the proportion of methane oxidizers in the cultures nor the versatility of the organisms in oxidizing other gases and ammonia have been determined. Enrichments in CH_4 and methanol-containing media with the intent of isolating pure cultures have resulted in a predominance of bacteria having homogeneous morphological characteristics. However, due to the mixotrophic nature of the cultures (oxidize CH_4, Mn^{2+} and NH_4^+), we are not yet positive of their purity.

The generation times of the mixed cultures at 100 °C in a medium containing S, Mn, Fe and $NaHCO_3$ ranged from 37 to 65 min (Table 3). The bacteria associated with the hottest water sample (982 7/8 at 304 °C) also had the shortest generation time. The lack of any measurable lag phase in the growth of these cultures at 100 °C might help explain their rapid production of CH_4 and H_2 (Table 2). Within 12–15 h incubation, the total numbers of bacteria remained constant at $\sim10^9$ cells ml^{-1}, although morphologically distinct groups continued to replace other groups for up to 2 weeks. Rod-shaped bacteria (1–2 μm) and small cocci (0.5–0.7 μm) dominated young cultures (up to 7 h) whereas in older cultures, sheathed, budding and filamentous bacteria, and a coccus having spines, were observed.

Because very few microorganisms have been described which can grow above 90 °C and only one species has been shown[13–16] to grow above 100 °C, it is probable the vent thermophiles are new species. For example, the highest growth temperature previously reported for a methanogen and a methylotroph are ~70 and 55 °C, respectively[14,17]. Also, because of the uniqueness, of these marine thermophiles, nothing is known about the biochemical reactions involved in their formation of H_2, CH_4 and CO. The elucidation of these metabolic pathways awaits the isolation of pure cultures. Due to the growth temperature characteristics of these communities and their propensity to form clumps and sheaths, it has been difficult to obtain pure cultures.

Table 3 Growth rates and rates of methane oxidation by 21 °N thermophilic bacterial communities at 100±2 °C

	Growth rate			Methane oxidation rate	
Sample	Time (h)	No. of bacteria ($\text{ml}^{-1}\times10^4$)	Generation time (min)	^{14}C-CH$_4$ oxidized to CO$_2$ (nmol h^{-1})	Inoculum size (no. bacteria per 50 ml)
978 5/6 (water)	0	1.2	55	2.3	3.0×10^7
	2	4.0			
	3.5	34			
	7	98

	2	10			
	3.5	25			
	7	120			
	11	3,700			

Growth rates of bacterial communities at 100 °C were determined using epifluorescent microscopy. The growth medium was MS with 0.5% HEPES buffer supplemented with 0.2% $Na_2S_2O_3\cdot5H_2O$; 0.02% $MnSO_4\cdot H_2O$; 0.02% $FeSO_4\cdot7H_2O$; 0.05% $(NH_4)_2SO_4$; 0.01 $Ca(NO_3)_2$ 0.05% Na_2HPO_4; 0.05% $NaHCO_3$; trace element mix (see Table 1 legend); 0.001% Bacto-yeast extract (Difco) and adjusted to *p*H 7.0±0.2. Yeast extract to 0.001% was found to stimulate growth of the communities. Higher concentrations were inhibitory. The component(s) in yeast extract responsible for this growth response is not known. Growth rates were determined from duplicate 100-ml cultures in 150-ml screw-cap bottles. 10-ml subsamples from each culture were used in all the bacterial count measurements. Methane oxidation rates were measured using ^{14}C-CH$_4$ at a final concentration of 1 μCi ml^{-1} (50 mCi mmol^{-1}). The bacterial cultures were grown in MS supplemented with trace element mix, 0.02% $NaNO_3$; 0.03% Na_2HPO_4; 0.02% $MnSO_4$ H_2O; 0.5% HEPES buffer in 60-ml serum bottles containing 25 ml medium with a gas mixture consisting of 20% methane and 80% air. After 24 h incubation at 100 °C, the cultures were brought up to a volume of 50 ml with MS medium, flushed for 2 min with air, capped and 1 ml of ^{14}C-CH$_4$ was added. Three sets of triplicate samples were run for each culture and the rates of methane oxidation were measured after 1, 2 and 4 h. Oxidation of methane was terminated by adding 1 ml of 10 M NaOH. The samples were then transferred to 100-ml serum bottles fitted with rubber caps according to the procedures of Harrison *et al.*[26] and the ^{14}C-CO$_2$ was collected on β-phenylethylamine-impregnated filter paper. The level of ^{14}C-CH$_4$ incorporated into cells was determined as previously described[27]. All samples were counted using a Beckman LS 100-C scintillation counter in 10 ml toluene fluor (Omnifluor, NEN). All counts were corrected for counting efficiency by the channel-ratio method. In general, about 1–5% of the total ^{14}C-CH$_4$ taken up by these communities was incorporated into cellular material.

One of the important questions regarding the oxidative microbial activity in anaerobic submarine hydrothermal waters is the nature, source and concentrations of the electron acceptors. Oxygen and NO_3^-, the most abundant electron acceptors in ambient seawater, were either not detected or were present in low concentrations in waters from the Galapagos vents[4] or from 21° N chimneys (J. Edmond, personal communication). However, due either to the leaky nature of hydrothermal systems or to advection processes, it is possible that O_2 and NO_3^- are involved. As these electron acceptors would be the factors which most limit bacterial productivity, they would be rapidly utilized *in situ*. Many of the sulphur- and manganese-oxidizing bacteria isolated from the Galapagos and 21° N waters and animals are capable of coupling oxidation reactions with denitrification (J.A.B. unpublished data). An alternative hypothesis would be that other electron acceptors such as MnO_2 and N_2O could be abiogenically synthesized in hydrothermal waters.

Even though the temperatures of some water samples harbouring thermophiles were above 300 °C, we cannot conclude that these bacteria grow in those super-heated waters. As previously stated, seawater at the depths of these environments can remain liquid at temperatures up to 460 °C (ref. 7). Also, in some cases increased hydrostatic pressure can affect microorganisms in a manner analogous to a decrease in temperature[18]. Further experiments are needed to test the possibility that these thermophiles can grow in super-heated water at pressures equivalent to water depths of 2,500–3,000 m. Determining the maximum and optimum growth temperatures under such *in situ* pressures will help to characterize the distribution of actively growing thermophiles in submarine hydrothermal environments.

Although we do not know the extent to which microorganisms are contributing to the quantity of CH_4, H_2 and CO venting from hydrothermal systems, our preliminary findings indicate that these gases may not be produced entirely by abiogenic reactions. Particularly in the lower temperature vents, microbial formation of these gases may be very significant, but even in the high temperature vents at 21° N, this mechanism cannot be ruled out.

Finally, it has been suggested that the first group of microorganisms to evolve in the warm Archaean oceans were thermophiles and that submarine hydrothermal environments could be suitable sites for chemical and microbiological evolution to occur[19,20]. It is tempting, therefore, to suggest that some of these present day marine hydrothermal vent thermophiles may represent physiological analogues to Archaean ocean bacteria.

Support for this research was provided by Office of Naval Research grant N00014-79C-0004 and NSF grant 79-27283. We also thank the crews of the R/V *Lulu* and R/V *Gillis* for their assistance, John Edmond for his invitation to participate on the expedition and for use of unpublished data, R. Y. Morita for use of laboratory facilities, and Clifford Dahm and Sarah Hoffman for their helpful discussions and editorial comments.

Evidence that patterning mechanisms in developing and regenerating limbs are the same

Ken Muneoka & Susan V. Bryant

Developmental Biology Center and Department of Developmental
and Cell Biology, University of California, Irvine,
California 92717, USA

Some amphibians have the ability to form new limbs throughout their lives. The essential similarity between limb regeneration and the original development of the limb is that both involve the elaboration of new patterns of structures. While some investigators believe that the two developing systems use similar mechanisms to generate the limb pattern[1-7], others have stressed the basic differences in developing and regenerating limbs, and have concluded that different mechanisms exist[8]. Both developing and regenerating urodele limbs can be caused to form supernumerary parts following tissue misalignment so that cells from normally disparate positions within the limb circumference confront each other (developing limbs[2,9,10]; regenerating limbs, see ref. 11 for review). If similar mechanisms are operating, the developing limb should respond to grafts of regenerating limb tissue, and vice versa, by forming supernumerary outgrowths. If different mechanisms are operating, either the grafts should fail or the response should be disorganized. Our results with the axolotl *Ambystoma mexicanum* suggest that the patterning mechanisms are the same.

Grafts between regenerating fore- and hindlimbs are as effective as grafts within the homologous limb in eliciting supernumerary limb formation[12,13]. Similar conclusions can be drawn from experiments performed on the developing leg and wing buds of birds[14-16]. We exploited this in our experiments on the axolotl where development of the hindlimb is retarded relative to that of the forelimb[17], thus enabling grafts to be made between animals of similar age in which the hindlimb is developing and the forelimb is regenerating. Forelimbs were amputated midway through the humerus at stage 46[17] and allowed to regenerate to the stage of palette[18]. Stage 46 hindlimb buds were amputated near the base and exchanged with palette stage blastemas removed from older sibling larvae. A section through a developing hindlimb bud at stage 46 is shown in Fig. 1. The limb bud is undifferentiated at this stage. In the experimental series, contralateral grafts were made between developing and regenerating limbs so as to confront anterior and posterior tissue. In the controls, ipsilateral grafts were made between developing and regenerating limbs so as to align all circumferential positions. In addition, developing hindlimb buds were grafted either contralaterally (experimentals) or ipsilaterally (controls) to other hindlimb bud stumps (Fig. 2).

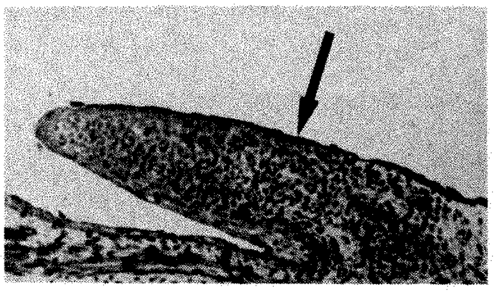

Fig. 1 A longitudinal section through a stage 46 hindlimb bud of the axolotl. No histological differentiation has yet occurred. The arrow indicates the level at which the limb bud was cut. Limbs were fixed in Bouin's and embedded in paraffin for serial sectioning. Sections were cut at 6 μm and stained with Mallory's triple stain. ×70.

The results are shown in Table 1. Control grafts, in which no positional disparity was created by grafting, mostly developed into normal limbs without supernumerary structures (Fig. 3*a*–*c*). In 3 out of 41 cases (one forelimb blastema to hindlimb bud stump and two hindlimb buds to forelimb blastema stumps), one extra digit formed at the anterior and/or posterior margin of the graft. The remaining 38 cases formed normal limbs according to the site of origin of the graft.

In the experimental series, where grafting created tissue disparities, supernumerary limbs formed in a high percentage of cases (Table 1). Contralateral exchange of developing hindlimb buds led to supernumerary limbs in 73% of the cases (Fig. 3*f*). Contralateral grafting of developing hindlimb buds to regenerating forelimb stumps led to supernumerary limbs in 70% of the cases (Fig. 3*d*), and the reciprocal experiment of contralateral grafting of regenerating forelimb blastema to developing hindlimb bud stump led to supernumerary limbs in 62% of the cases (Fig. 3*e*). In all the experimental series, extra structures formed either at the anterior, the posterior, or both borders of the graft junction (see Table 1), and in all cases the supernumerary limbs were of stump rather than graft handedness. Commonly, supernumerary limbs were not clearly separated from the grafted limb, and loss of digits along the line of symmetry between supernumerary and grafted limb was observed (see Fig. 3*e*). Similar types of limbs were observed by Iten and Bryant[19] after contralateral grafts of early stage forelimb blastemas of newts (*Notophthalmus viridescens*) to appose anterior and posterior tissues. How such fusions can occur is discussed in terms of the polar coordinate model by Bryant *et al.*[3].

The results of these experiments show that the interactions between developing and regenerating limbs of urodeles following confrontations between cells from disparate positions are similar to the interactions between similar limb bud and limb bud or blastema and blastema grafts. When developing axolotl forelimb buds were exchanged contralaterally to appose anterior and posterior tissues, Maden and Goodwin[9] found that 70% of the cases produced limbs with supernumerary structures. Our results on the developing hindlimb bud are very

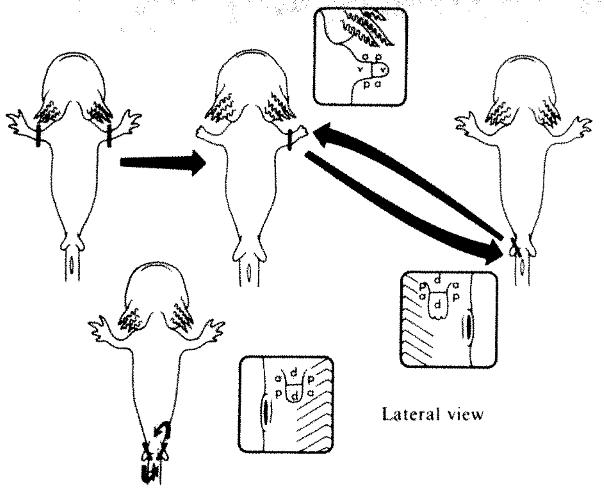

Fig. 2 Diagram of the grafting operations, shown here from the ventral aspect. *a*, The forelimbs of stage 46 (ref. 17) axolotls were amputated through the mid-humerus. Note that the forelimbs in the axolotl are fully differentiated when the hindlimbs are just beginning to grow out. After a period of 10–12 days the forelimb blastemas had regenerated to the stage of palette to early digits[18]. These animals were paired with more slowly developing stage 46 sibling axolotls. The regenerating forelimb blastema and the developing hindlimb bud were exchanged between the paired animals (usually between differently pigmented animals). Grafts were made either ipsilaterally (control series) matching anterior, posterior, dorsal and ventral limb tissues or contralaterally (experimental series) apposing anterior and posterior limb tissues. A contralateral graft is shown in the diagram. The insets show a closer ventral view of the limb bud to blastema stump graft and a lateral view of blastema to limb bud stump graft. *b*, The hindlimb buds of a stage 46 axolotl were exchanged either contralaterally (experimental series) as shown here, or simply amputated and replaced (control series). In the experimental series, the limb buds were oriented to appose anterior and posterior limb bud tissue while keeping dorsal and ventral limb bud tissue aligned. For all grafting operations animals were anaesthetized in MS222 (Eastman) diluted 1:3,000 in 50% Holtfreter solution. Operations were done in air with fine irridectomy scissors, forceps and microdissection scalpel. Operated animals were kept in individual dishes (100×25 mm plastic Petri dishes, Lab-tek), fed and changed daily, and checked (without anaesthetizing) every 2–3 days throughout the experiment. Camera lucida drawings were made every time the grafts were checked. In this way observations on the early stages of limb outgrowth were made and the positions of supernumerary outgrowths were recorded. a, Anterior; d, dorsal; p, posterior; v, ventral.

similar, with 73% of the cases producing supernumerary structures. Similar experiments by Thoms and Fallon[10] on the developing forelimb buds of three species of urodeles (*A. mexicanum*, *Ambystoma maculatum* and *N. viridescens*) resulted in supernumerary structures in 95% of the cases. Experiments by Tank[20] on the regeneration blastema of *A. mexicanum* grafted to oppose anterior and posterior tissues showed that supernumerary structures were produced in 57% of the cases. Iten and Bryant[19] showed in similar experiments in the newt that supernumerary structures were formed in 63% of the cases. In all these experiments on developing and regenerating limbs the position and handedness of the supernumerary structures which formed were similar, and are consistent with the polar coordinate model[3,5]. These results, taken with those reported here, suggest that the developing and regenerating limbs of urodeles use similar mechanisms for pattern regulation during limb outgrowth.

It also appears from grafting of developing limb bud tissues from evolutionarily diverse vertebrate species into the chick wing bud, that common pattern regulatory mechanisms are shared among many different vertebrates[14,21–23]. In these studies grafts of tissue from the posterior of the limb buds of mammals (man, hamster, mouse, pig and ferret), birds (Japanese quail, ringneck pheasant, chukar partridge and Peking duck) and reptiles (snapping turtle and painted turtle) into the anterior of chick wing buds resulted in the formation of supernumerary limb structures. Further, control grafts which were made so that no positional disparity was created resulted in the normal development of the host limb. The relationship between the developing amphibian limb bud and the developing chick limb bud is less clear because differences in the temperature tolerances of the two species make grafting experiments between them difficult to interpret[23]. However, grafting studies on the amphibian limb bud show that its behaviour after apposition of normally nonadjacent tissues is remarkably similar to that of the chick limb bud[2,9,10,24]. It seems therefore that the mechanisms of pattern formation in the development of vertebrate limbs are common to all vertebrates[22]. Our results here suggest that those patterning mechanisms common to vertebrate limb development are also the mechanisms that control patterning during limb regeneration in amphibians.

This conclusion may have important implications for the way we think about how the vertebrate limb pattern is formed as

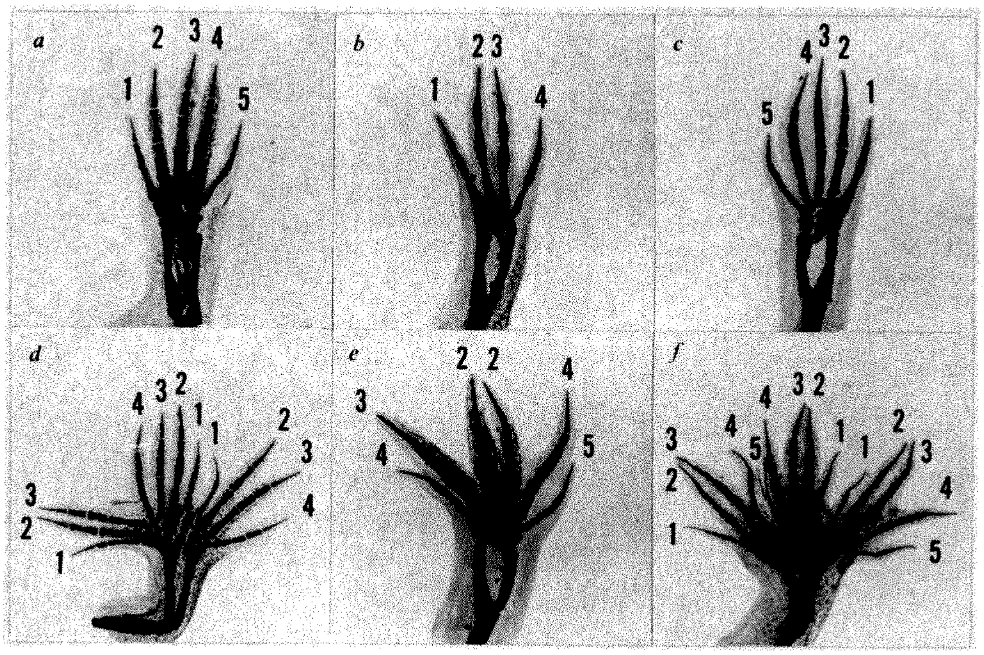

Fig. 3 Skeletal preparations of control and experimental limbs, prepared by the Victoria blue technique[25] 4 to 6 weeks after the grafting operation. *a*, A control ipsilateral graft of a developing right hindlimb bud put onto a regenerating right forelimb stump. A normal five-digit right hindlimb was formed on the forelimb stump. *b*, A control ipsilateral graft of a right regenerating forelimb blastema put onto a developing right hindlimb bud stump. The graft produced a normal four-digit right forelimb on the hindlimb stump. *c*, A control ipsilateral graft of a developing left hindlimb bud put onto a developing left hindlimb bud stump. The resulting limb is a normal five-digit left hindlimb. *d*, A limb which resulted from the contralateral graft of a left developing hindlimb bud to a right regenerating forelimb blastema stump. Supernumerary limb structures are present both anterior and posterior to the grafted hindlimb. *e*, A limb which resulted from the contralateral graft of a left regenerating forelimb blastema onto a right developing hindlimb bud stump. Digits derived from the graft are located on the left of the figure; supernumerary limb structures are present on the right. The two limbs have fused during outgrowth with loss of digits along the line of symmetry between them. *f*, A limb resulting from a contralateral graft of a left developing hindlimb bud to a right developing hindlimb bud stump. Supernumerary limb structures are present both anterior and posterior to the grafted hindlimb. *a–f*, ×5.

limb development and limb regeneration have mostly been regarded as two very different fields of study. Models of pattern formation during limb development have been drawn solely from data generated from work on limb development and the same is true for most models of pattern formation during limb regeneration. As there is now direct evidence that the mechanisms controlling pattern formation during limb development are the same as those for limb regeneration, we believe that the experimental data from both limb development and limb regeneration studies must be considered together to understand pattern formation. Why all vertebrates can develop limbs, but only a few can regenerate them remains puzzling. However, we propose that during evolution, the underlying patterning mechanisms have remained the same, but that the ability to call these mechanisms into use has been modified. In other words, the urodele limb can regenerate because it has maintained its ability to implement pattern mechanisms whereas the chick wing cannot regenerate because it loses this ability very early in its development.

These studies therefore show that it is possible to learn about limb development by studying limb regeneration. Conversely, studies of limb development may help us to understand the causes of failure of limb regeneration in higher vertebrates.

Selective collateral elimination in early postnatal development restricts cortical distribution of rat pyramidal tract neurones

Brent B. Stanfield, Dennis D. M. O'Leary & Carl Fricks

The Salk Institute for Biological Studies and The Clayton Foundation for Research—California Division, PO Box 85800, San Diego, California 92138, USA

The pyramidal tract, comprising those axons which pass from the neocortex to the medulla and spinal cord, is among the most thoroughly studied projections of the mammalian cortex. Recent studies using anterograde axon tracing techniques have provided information concerning the time course of the growth of pyramidal tract fibres[1,2], yet much remains to be learned about its development. We have now begun to study the distribution of the neurones of origin of the pyramidal tract during the postnatal development of the rat neocortex using the recently introduced retrogradely transported fluorescent marker, True blue[3]. During the first postnatal week, injections of True blue into the pyramidal decussation result in the labelling of pyramidal tract neurones which are distributed virtually throughout the tangential extent of layer V of the neocortex, whereas after comparable injections during the fourth postnatal week the distribution of such cells is much more restricted and remains restricted into adult life. This developmental restriction is most dramatic in the occipital cortex: during the first postnatal week many pyramidal tract neurones are found throughout the visual cortex while none is seen in this area in the adult. When True blue is injected into the pyramidal decussation during the first postnatal week and the animals are allowed to survive until the fourth postnatal week, the distribution of pyramidal tract neurones is as widespread as in the immediate postnatal period and includes the entire visual cortex. This implies that many of the neurones in the occipital cortex initially send a collateral into the pyramidal tract which is later eliminated, although the neurones themselves persist. These findings, together with similar recent observations on the development of the callosal connections[4,5], indicate that the elimination of axon collaterals may be a general feature of the development of cortical projection systems, and that such transitory collaterals may traverse considerable distances.

The experimental procedure in all instances involved the injection of 0.3–1.0 μl of the fluorescent dye (a 2–5% solution of True blue) into the pyramidal tract at the level of its decussation at the spino-medullary junction. This injection site is convenient because: (1) of the ease with which consistent injections can be made; (2) of the considerable distance between this site and the targets of non-pyramidal tract cortical neurones; (3) it is known that in the rat the fibres of the pyramidal tract have reached the decussation at the time of birth[2,6]. The pyramidal decussation of the rat consists of corticospinal axons (which after crossing descend into the spinal cord) and crossed corticobulbar fibres which terminate in the dorsal column and other medullary nuclei[7,8]. Thus, we will refer to the retrogradely labelled cortical neurones in our experiments as pyramidal tract

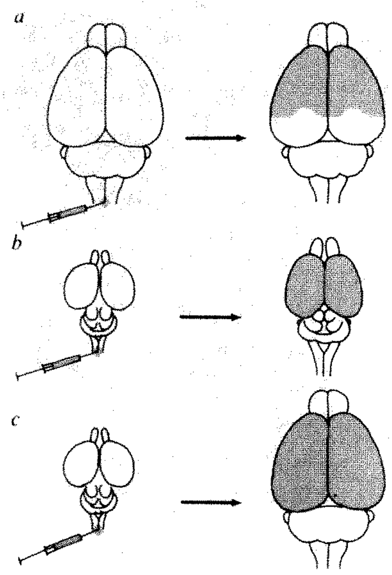

Fig. 1 Schematic illustrations of the three experimental paradigms used in this study, summarizing the results of each. *a*, When True blue is injected into the pyramidal decussation of adult rats, or rats at 20 days of age, the distribution of retrogradely labelled pyramidal tract neurones is widespread but limited to about the rostral two-thirds of the cerebral hemisphere. *b*, *c*, Following similar injections in 2-day-old rat pups, labelled cells are spread throughout the tangential extent of the cortex, whether the animals are killed on day 6 (*b*) or are allowed to survive until day 25 (*c*).

0028-0836/82/290371—03$01.00

neurones without distinguishing between the corticobulbar and corticospinal projections because both of these had access to the injected label. After a suitable survival period the animals were perfused with 10% buffered neutral formalin, the brains were removed and processed as described elsewhere[9] and the frozen sections were examined with a Leitz Dialux-20 fluorescence microscope.

Following injections of True blue (0.5–1.0 μl) into the pyramidal decussation of adult rats ($n = 7$), the distribution of labelled cells in the cortex after a 5–7 day survival period is similar to, but more extensive than, that of corticospinal cells, as recently shown through the use of similar techniques[10,11]. Although strictly limited in the radial dimension of the cortex to layer V (as identified in adjacent Nissl-stained sections), the labelled neurones occupy a large and continuous tangential sheet of cortex. This sheet of labelled cells spans virtually the entire frontal cortex and extends uninterruptedly into the parietal cortex (Fig. 1*a*). An essentially identical distribution of pyramidal tract neurones is seen in rats that are injected on postnatal day 20 and allowed to survive for 5 days ($n = 14$). We emphasize that although the extent of the cortex in which pyramidal tract neurones are found varies slightly from case to case (due no doubt to slight variations in the effective injection site), in none of these animals, nor in any of the adult cases, are retrogradely labelled neurones identifiable in the occipital cortex (Figs 2*a*, 3*a*).

In animals injected with True blue (0.3–0.5 μl) on postnatal day 2 and killed on postnatal day 6 ($n = 17$), a large number of retrogradely labelled cells can be seen in layer V of the cortex (Fig. 3*b*). In fact, the density of labelled cells in the early postnatal cortex is appreciably greater than that in the older animals. The band of labelled cells is spread across essentially the entire tangential extent of the cortex, from the frontal cortex to the caudal pole of the hemisphere (Fig. 1*b*). We emphasize that in none of the present experiments did the injected dye spread beyond the lower medulla and that we are confident that there was no involvement of the corticopontine projection.

Thus, during the first week of postnatal life pyramidal tract neurones seem to be confined to layer V, but are distributed throughout the tangential extent of the neocortex, whereas by the fourth week such cells are excluded from the posterior pole of the hemisphere, and in particular from the visual cortex[12,13]. This difference in the distribution of pyramidal tract neurones at these two ages is most clearly seen in sagittal sections as shown in Figs 2 and 3. To determine whether the developmental restriction in the distribution of pyramidal tract neurones is brought about by the selective elimination of axon collaterals or by cell death, in 15 animals we injected True blue (0.3–0.5 μl) into the pyramidal decussation on postnatal day 2 and allowed the rats to survive until postnatal day 25. As we have previously reported[5], True blue remains within labelled neurones for several weeks, without significant degradation or leakage. In these experiments the distribution of labelled cortical neurones is as widespread as that in animals which were injected on postnatal day 2 and allowed to survive for only a few days even though the adult distribution of pyramidal tract neurones is established by the time these animals were killed on day 25 (Fig. 1). Of course, the cortex in these animals had continued its normal course of maturation and was cytoarchitectonically indistinguishable from that of control animals of the same age. The band of retrogradely labelled neurones was again confined to layer V, but extended throughout the cortex, including the visual cortex, from which, as we have shown, pyramidal tract neurones are normally excluded by the fourth postnatal week (Figs 2, 3).

The most straightforward interpretation of these findings is that early in postnatal life there are neurones throughout the tangential extent of layer V which send axons into the pyramidal tract, and that during the next 3 weeks many of these cells (and especially those in the visual cortex) lose their pyramidal tract collaterals even though the neurones themselves survive. At present we cannot rule out the possibility that neuronal cell death also contributes to the exclusion of pyramidal tract neurones from the occipital cortex during postnatal development, but certainly this restriction is not due mainly to the death of these neurones, because when labelled by way of their pyramidal tract axon on postnatal day 2, many of these cells are still identifiable at 4 weeks of age. This result also excludes the possibility that the developmental change in the distribution of labelled neurones is due to a secondary, tangential migration of neurones. Although we cannot determine how many neurones lose pyramidal tract collaterals during postnatal development, within the occipital cortex collateral elimination is clearly a substantial event as it results in the disappearance of all pyramidal tract axons which initially arise from this part of the cortex.

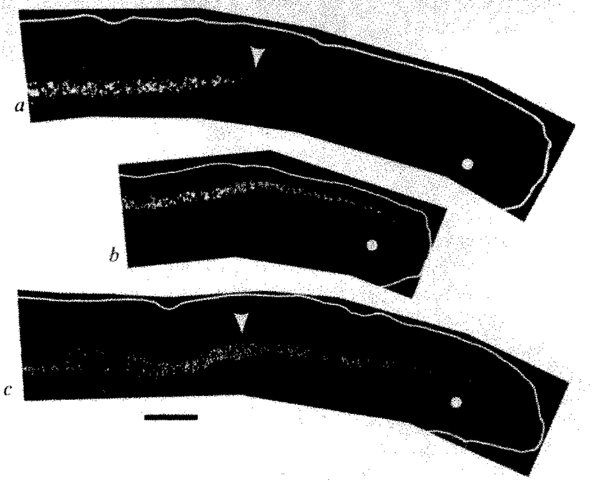

Fig. 3 These photomontages illustrate the distribution of True blue-labelled neurones in sagittal sections of the caudal part of the cortex from animals injected in the pyramidal decussation: *a*, at postnatal day 20 and surviving until postnatal day 25; *b*, at postnatal day 2 and surviving to postnatal day 6; *c*, at postnatal day 2 and surviving until postnatal day 25. The white line indicates the cortical surface; the splenium of the corpus callosum is marked with a large dot. The arrowhead in *a* marks the caudal limit of the band of labelled cells and that in *c* is at the same level. Scale bar, 1 mm.

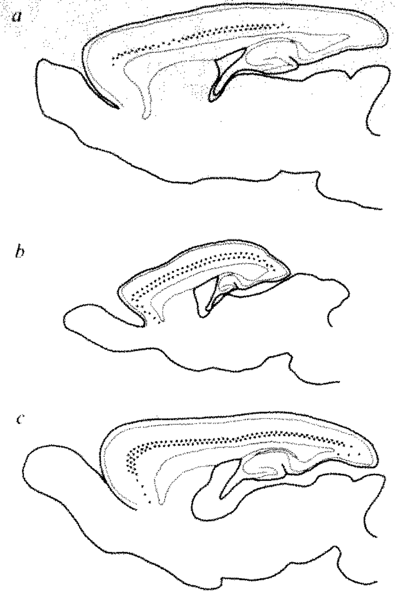

Fig. 2 Tracings of sagittal sections of rat brains at approximately the same medio-lateral position to show the distribution of retrogradely labelled neurones in the cortex of animals which: *a*, received an injection of True blue in the pyramidal decussation on postnatal day 20 and was killed on postnatal day 25; *b*, received a similar injection on postnatal day 2 and was killed on postnatal day 6; *c*, was injected on postnatal day 2 and killed on postnatal day 25. Each dot represents ~15 labelled neurones.

These observations on the development of pyramidal tract neurones are similar to those that we and others have recently made on the development of callosally projecting neurones[4,5]. In that instance, however, the developmental change results in a refinement of the distribution of callosal neurones within an area, whereas in the present study we have shown the complete elimination of a substantial projection from an entire region of cortex. However, together these studies suggest that a loss of collateral projections may be a rather general feature of the development of cortical efferent systems. We have not examined the time course of the restriction in the distribution of pyramidal tract neurones in detail, but the data available so far suggest that it is similar to that affecting the distribution of callosal neurones in the rat[14]. It would also be of interest to determine if some of early pyramidal tract collaterals reach and form synapses in the spinal cord before they are withdrawn. At present, it is not known whether collateral elimination of this type also involves synapse elimination—a phenomenon known to occur in several developing systems[15]. Interestingly in one of the systems in which synapse elimination has been shown to occur, there is apparently no change in the number of neurones which give rise to these synapses[16]. Finally, we emphasize that during the first postnatal week, when the tangential distribution of the pyramidal tract neurones is widespread, their radial distribution within layer V has already been determined.

Glycogenolysis induced by serotonin in brain: identification of a new class of receptor

T. T. Quach, C. Rose, A. M. Duchemin & J. C. Schwartz

Unité de Neurobiologie (U 109), Centre Paul Broca de l'INSERM, 2ter rue d'Alésia, 75014 Paris, France

Serotonin-containing neurones in brain have been proposed to have a role in the control of physiological mechanisms such as sleep, thermoregulation, pain perception and endocrine secretions as well as in the physiopathology of migraine or depressive illness[1–6]. One difficulty in testing these possibilities lies in the scarcity of pharmacological agents able to interact selectively with the probably multiple classes of serotonin receptors in the central nervous system. Development of such agents would be facilitated by simple *in vitro* models in which biological responses to serotonin in mammalian brain could be quantified. Thus a serotonin-sensitive adenylate cyclase has been characterized in rat brain, but the response to serotonin is weak in newborn and practically absent in adult animals[7–11]. In addition, two pharmacologically distinct classes of serotoninergic binding site have been identified using ^{3}H-serotonin and ^{3}H-spiperone as ligands[12–17], but their identification as receptors remains to be established. More recently, serotonin has been shown to stimulate phosphorylation of a neuronal protein in slices from the facial motor nucleus, although the receptors mediating this action were not characterized[18]. We now report that serotonin stimulates glycogen hydrolysis in slices of cerebral cortex, that this action is mediated by a novel class of receptors and that tricyclic antidepressants are among the best competitive antagonists of the indolamine.

The addition of serotonin to slices from mouse cerebral cortex preincubated with ^{3}H-glucose for 30 min, at a time when ^{3}H-glycogen level in tissue has reached a plateau[19], results in rapid hydrolysis of the ^{3}H-polymer. The serotonin-induced glycogenolysis is concentration dependent, occurs with a K_{act} of 20 ± 3 μM and reduces the ^{3}H-glycogen level by, at the most, $78 \pm 4\%$ (Fig. 1*a*). A similar effect is observed with other indolamine derivatives such as tryptamine or 5-methoxytryptamine, while tryptamine derivatives *N*-methylated on the side chain, such as *N*-methyltryptamine, bufotenine, psilocybin and psilocin, are only partially active and *N,N*-dimethyltryptamine is totally inactive (Fig. 1*a*, *b*). This latter observation prompted us to study *N,N*-dimethyltryptamine as antagonist: we found that increasing concentrations of this compound shift the concentration–response curve to serotonin rightwards, without modifying the maximal response (Fig. 2). This suggests that *N,N*-dimethyltryptamine acts as a competitive antagonist with

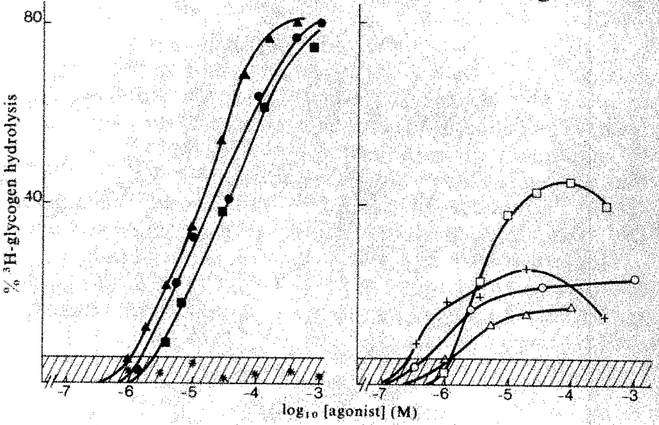

Fig. 1 ^{3}H-glycogen hydrolysis induced by serotonin and other tryptamine derivatives in slices from cerebral cortex. Male Swiss albino mice (18–20 g, Lessieux, France) were killed by decapitation, the cerebral cortex was quickly removed and slices (250 × 250 μm thick) were prepared in a cold room (4 °C) with a McIlwain tissue slicer. Pooled cortical slices from six animals were preincubated for 15 min at 37 °C in a slightly modified Krebs–Ringer bicarbonate medium (120 mM NaCl, 5 mM KCl, 2.6 mM $CaCl_2$, 0.67 mM $MgSO_4$, 1.2 mM KH_2PO_4, 3 mM glucose and 27.5 mM $NaHCO_3$) under a constant stream of O_2/CO_2 (95:5). The slices were then washed once with fresh medium, 300-μl aliquots of the tissue suspension corresponding to 0.5 mg protein were distributed in incubation tubes and 13.4 nmol of ^{3}H-glucose (500 mCi mmol^{-1}; Amersham) were added in a volume of 10 μl. Test agents were added when ^{3}H-glycogen level in tissue had reached a steady state, that is, after a 30 min incubation[19], and the slices were further incubated for 20 min. The incubations were stopped by rapid centrifugation. The supernatant was discarded and replaced by 300 μl of fresh medium in which the slices were sonicated. A fraction of the resulting homogenate was then immediately deproteinized by heating at 95 °C for 10 min and ^{3}H-glycogen assayed by the ethanol filter paper technique[19]. Results are expressed as per cent of the basal ^{3}H-glycogen level (26.3 ± 2.1 d.p.m. $\times 10^3$ per mg protein). The shaded area corresponds to the s.e.m. of basal ^{3}H-glycogen level. Values are the mean of 15–25 determinations performed in 3–5 independent experiments. ▲, Serotonin; *, *N,N*-dimethyltryptamine; ●, 5-methoxytryptamine; ■, tryptamine; △, *N*-methyltryptamine; +, bufotenine (5-hydroxy-*N,N*-dimethyltryptamine); ○, psilocybin (*O*-phosphoryl-4-hydroxy-*N,N*-dimethyltryptamine); and □, psilocin (4-hydroxy-*N,N*-dimethyltryptamine).

an apparent K_i of 0.8 μM. The ergot derivative (+)LSD can elicit complete ^{3}H-glycogen hydrolysis but only at high concentrations; its action was also antagonized by *N,N*-dimethyltryptamine with an apparent K_i in the micromolar range. Typical serotoninergic antagonists such as methysergide, cyproheptadine and methiothepin fail to or weakly block the serotonin-induced response (Table 1).

Among neuroactive drugs, the antipsychotics chlorpromazine, spiperone, pipamperone and pimozide antagonize the serotonin-induced glycogenolysis with inhibition constants of between 4 and 20 μM; various tricyclic antidepressant compounds competitively block this response, all with inhibition constants of ~1 μM.

The glycogenolytic response elicited by serotonin in cortical slices suggests that this amine should be added to the list of neurotransmitters controlling carbohydrate metabolism in brain and which comprises the other glycogenolytic agents noradrenaline[19-21] (via β_1 receptors), histamine[22] (via H_1 receptors) and the neuropeptide vasoactive intestinal peptide (VIP)[23]. The serotonin-induced glycogenolysis requires higher concentrations of amine, however, particularly in comparison with VIP. Because the response to these agents occurs in the same cells (as shown by the almost total ^{3}H-glycogen hydrolysis in all cases), lower serotonin concentrations might be expected to be required in the presence of other glycogenolytic agents.

In a preparation such as brain slices, an effect observed with one neurotransmitter could be indirectly mediated by the release of another. The lack of antagonism by β-adrenergic and H_1-receptor blockers (Table 1) indicates that neither noradrenaline nor histamine is involved. Experiments with phosphodiesterase inhibitors or with various concentrations of calcium indicate that phosphorylase activation leading to glycogen hydrolysis seems to result in brain[20-22], as in other tissues[24-26], from one of two mechanisms: stimulation of an adenylate cyclase, as in the case of noradrenaline[19,20] and VIP[23], or translocation of calcium ions, as in the case of histamine[22]. The former mechanism is probably not involved in the response to serotonin as it is not modified in the presence of 0.7 μM isobutyl methylxanthine, a phosphodiesterase inhibitor, but is diminished when the calcium concentration is lowered (not shown). This suggests that VIP is probably not indirectly responsible for the serotonin effect, but this requires confirmation with antagonists of the neuropeptide, which are not available.

Serotonin induces phosphorylation of the 'protein I' in slices from facial motor nucleus at similar concentrations to those required for the glycogenolytic response, and both responses are blocked by 10 μM mianserin; however, only the former is potentiated by isobutyl methylxanthine[18]. Among the several other unidentified proteins which were phosphorylated in response to serotonin, one may correspond to phosphorylase.

Glycogen is the single largest energy reserve in the brain and the glycogenolytic effect of serotonin should result in an increased availability of glucose. The cellular location of this response remains to be identified, however, as the polymer is present both in neuronal and glial elements[27]. Nevertheless the observations that impairment of monoaminergic neurotransmission in mice subchronically treated with reserpine results in the development of hypersensitivity to the glycogenolytic actions of noradrenaline[20] as well as to those of serotonin (T.T.Q., C.R., A.M.D. and J.C.S., in preparation) suggest that the target cells are tonically controlled by the two monoaminergic systems. Interestingly, the three aminergic systems controlling glycogenolysis—the coeruleo-cortical noradrenergic[28], the raphe-cortical[29] and the histaminergic ascending[30] projections—are highly divergent neuronal circuits emanating from restricted areas of the brain stem and projecting throughout the telencephalon. This common anatomical feature probably facilitates a coordinated, quasi-hormonal control of energy supply in large areas of brain.

The strong influence of small changes in the structure of agonists on their activity (Fig. 1) and the apparently competitive nature of the antagonism exerted by substances such as *N,N*-dimethyltryptamine (Fig. 2) suggest that serotonin-induced glycogenolysis is a receptor-mediated response. The pharmacol-

K_{act} values of compounds for ^{3}H-glycogen hydrolysis were obtained from the data of Fig. 1. K_i values were determined by one of two methods: (1) see Fig. 2. The rightward shift of the concentration–response curve to serotonin was determined in the presence of fixed concentration(s) of antagonists (concentrations indicated in parentheses) and the Cheng–Prussof equation[35] was then applied. (2) See Fig. 2 legend. The effect of 20 μM serotonin was antagonized by agents (indicated by *) in increasing concentrations and their K_i values were calculated from their IC_{50} values using the equation: $K_i = IC_{50}\,(1 + S/K_a)$. As shown for *N,N*-dimethyltryptamine in Fig. 2 legend, the two methods give K_i values which are always in good agreement, and the average is given. Concentration–response curves were established using six to eight concentrations of serotonin, agonists or antagonists (for each concentration 8–20 distinct determinations were performed in 2–5 separate experiments). Numbers in parentheses refer to references from which data were taken. NE, non-effective agents at the indicated concentration.

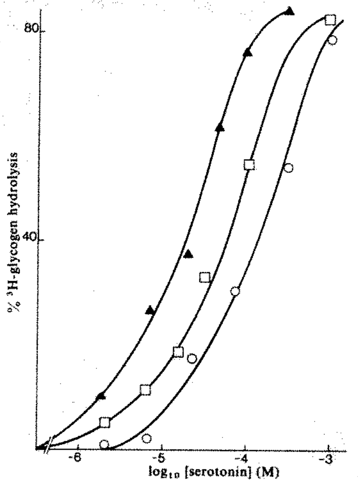

Fig. 2 Inhibition of the serotonin-induced glycogenolysis in slices from cerebral cortex by *N,N*-dimethyltryptamine. Following a 30 min preincubation in the presence of ^{3}H-glucose, serotonin was added at increasing concentrations and the incubation continued for a further 20 min. *N,N*-dimethyltryptamine was added 10 min before serotonin. Basal ^{3}H-glycogen level was 23.4 ± 1.2 d.p.m. $\times 10^3$ per mg protein. Values are the mean of 10–15 determinations performed in 2–5 independent experiments. The K_{act} values of serotonin alone or in the presence of *N,N*-dimethyltryptamine were determined by computer[36] and a K_i value of 0.8 µM was obtained from the equation. $K_i = I/[(K'_a/K_a) - 1]$, where K_a and K'_a are the K_{act} values of serotonin in the absence and presence of antagonist respectively, and I is the concentration of antagonist. In another experiment (not shown), using a fixed concentration of serotonin (100 µM) and increasing concentrations of *N,N*-dimethyltryptamine, the IC_{50} value of the latter compound was 10 µM, from which a K_i value of 1.7 µM was calculated from the equation[35]: $K_i = IC_{50}/(1 + S/K_a)$ where IC_{50} is the concentration of antagonist required to produce a 50% inhibition of the glycogenolytic effect of serotonin, S represents the concentration of serotonin and K_a is the K_{act} value of serotonin. ●, Serotonin; □, serotonin + 2×10^{-6} M *N,N*-dimethyltryptamine; ○, serotonin + 5×10^{-6} M *N,N*-dimethyltryptamine.

ogical specificity of the receptors mediating the serotonin-induced glycogenolysis does not correspond, however, to that of other serotoninergic receptors or putative receptors: for example, there are large differences in the apparent dissociation constants of the typical serotoninergic antagonists regarding inhibition of glycogenolysis, adenylate cyclase or binding of ^{3}H-spiperone or ^{3}H-serotonin respectively (Table 1). This suggests that a novel subclass of serotonin receptors mediates the glycogenolytic response.

It is unlikely that these receptors represent the common site of action of the potent hallucinogenic indole derivatives which display relatively low apparent affinity for the receptors and behave as either agonists (tryptamine) or antagonists (*N,N*-dimethyltryptamine). In view of the low apparent affinity of neuroleptics (compared with their affinity for dopamine receptors), it is also unlikely that significant occupation of serotonin receptors mediating glycogenolysis occurs during antipsychotic treatments which result in body fluid levels of these drugs in the nanomolar range[31]. On the other hand, micromolar concentrations of tricyclic antidepressants belonging to various chemical classes all antagonize competitively the serotonin-induced response. The antagonist effect of these compounds seems unrelated to their ability to block the serotonin uptake process as, for example, compounds such as iprindole or desimipramine are almost inactive on this process[32,33]. Because the effective concentrations of tricyclic compounds in the body fluids of patients undergoing antidepressant treatment seem to be in the micromolar range[34], it is likely that serotonin receptors mediating the glycogenolysis in brain are blocked during such treatments. It remains to be established whether this blockade participates in the antidepressant activity (or side effects) of these drugs.

Conventional antibodies have long been used in an attempt to produce specific neural markers[1,2]. Such markers would be invaluable for studying the structural organization and development of the nervous system. Unfortunately, they have not generally been found to discriminate satisfactorily between neuronal subpopulations[3,4]. Recent developments of the hybridoma technique[5], however, promise to provide monoclonal antibodies of adequate specificity. Such antibodies have already been generated and shown to be capable of distinguishing between individual neurones of the leech nervous system[6]. We report here two monoclonal antibodies which, although generated against human T cells[7,8], react exclusively with Purkinje cells in the vertebrate central nervous system (CNS). This new specificity arose out of a fortuitous observation made during examination of the lymphocyte infiltration of human cerebellar tumours with the monoclonal antibody, UCHT1. Although widely used as a T-cell marker, its reaction with neural tissue has not hitherto been described. To our knowledge, this is the first description of a monoclonal antibody which recognises a functionally discrete neuronal population in the vertebrate brain.

0028–0836/82/290375—03$01.00

UCHT1 is an IgG1 mouse monoclonal antibody, derived from a fusion between P3/NS1/1-Ag4-1 myeloma cells and splenic lymphocytes from BALB/c mice immunized with human infant thymocytes and Sezary cells. The antibody had been previously characterized in detail[7] and was thought to bind exclusively to an antigen of 22,000 molecular weight (MW) present on the surface of human T lymphocytes. Therefore, we were surprised that it produced strong staining of Purkinje cells, by indirect immunofluorescence, when applied to frozen sections of human cerebellum.

Purkinje cells provide the only efferent pathway from the cerebellar cortex, their axons terminating chiefly in the deep cerebellar nuclei[9]. Their large flask-shaped cell bodies and extensive dendritic arborizations give them a unique appearance. Figure 1 shows intense cytoplasmic staining of Purkinje cells by UCHT1, extending throughout axons and dendrites. Note that cerebellar granule, stellate, basket and glial cells fail to stain. Human, mouse, rat, guinea pig and quail brains produced identical Purkinje cell staining. No other cells were stained in the cerebrum, cerebellum or spinal cord of any of the species tested. Extensive screening of other non-lymphoid tissues revealed no further cross-reactivity. The specificity of UCHT1 staining is summarized in Table 1. Absorption experiments (Table 2) confirmed restriction of the UCHT1 neural antigen to the cerebellum. The discovery of Purkinje cell labelling by UCHT1 led us to investigate other anti-haemopoietic cell monoclonal antibodies for similar cross-reactivity (see Table 3). Of 12 reagents tested, only one (Leu-4; Becton Dickson) had anti-Purkinje cell activity. It produced cytoplasmic staining which was indistinguishable from that of UCHT1. Cross blocking experiments on human T lymphocytes (unpublished data) indicate that UCHT1, Leu-4 and another pan T-cell marker, OKT3[10] (Ortho Pharmaceuticals), recognize closely related antigenic determinants. It is, therefore, of special interest to note that OKT3 does not react with Purkinje cells.

Table 1 UCHT1 reactivity

Positive	Negative Human	 Other species
Human T cells	Erythrocytes	Rat:
		Cerebellum†
Human Purkinje cells	Polymorphs	Olfactory bulb
Mouse Purkinje cells	Monocytes	Cerebrum
Guinea pig Purkinje cells	Platelets	Midbrain

		Cerebellum†
	Primary cerebral tumours (25)	Cerebrum
	Secondary cerebral tumours (8)	Spinal cord

* Adult and 10-day-old neonates were tested.
† Cerebellum negative apart from Purkinje cells.

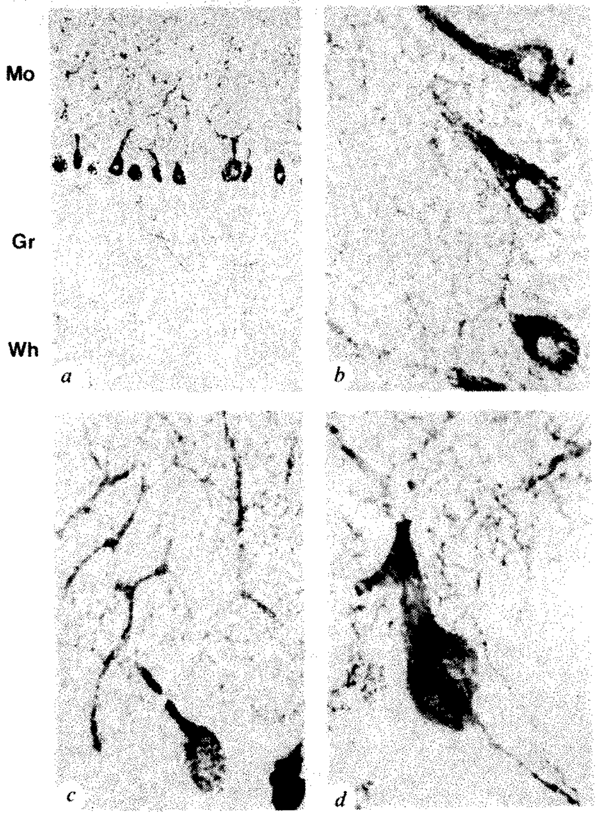

Fig. 1 Guinea pig Purkinje cells stained by UCHT1 using the indirect immunoperoxidase technique. Frozen sections (6 μm) of cerebellum were fixed briefly in acetone then incubated at 20 °C for 30 min with a purified IgG fraction of UCHT1 ascites, diluted 1:200. The slides were washed for 10 min in phosphate-buffered saline then incubated at 20 °C for 30 min with peroxidase-conjugated rabbit anti-mouse immunoglobulin (Dako), diluted 1:100. Diaminobenzidine (0.6 mg ml^{-1}) was used as the chromogenic substrate. *a* Shows Purkinje cell axons traversing the granule cell layer (Gr) to join other Purkinje axons of the cerebellar white matter (Wh). These axons were seen to terminate on neurones of the deep cerebellar nuclei. Such neurones showed no staining with UCHT1. Purkinje cell branching dendrites in the molecular layer (Mo) are clearly stained. *b*, The antigen is seen to be cytoplasmic, as the nuclei show no staining. *c* Shows the dendritic arborizations of the molecular layer; *d* shows an axon as it leaves the base of a Purkinje cell body.

The Purkinje cell antigen does not survive fixation in formaldehyde, paraformaldehyde, glutaraldehyde, osmium tetroxide, Carnoy's or Bouin's fixatives but is unaffected by fixation in acetone at room temperature for 5 min. The antigen is best demonstrated in fresh material but can be detected in sections stored for up to 3 days at −20 °C. Beyond this time, staining becomes unpredictable.

The relatively labile nature of the Purkinje antigen has so far prevented any determination of its molecular weight or biochemical characteristics. Without such data it is unsafe to assume that the UCHT1-defined Purkinje cell and T-cell antigens are identical[11,12]. Indeed, their differing species distributions and different locations within the cell (cytoplasm versus plasma membrane) suggest that they may be unrelated molecules which merely share a common antigenic determinant.

Although the nature of UCHT1-defined Purkinje specific antigen is unknown, it does not seem to match any of the other previously reported Purkinje cell-associated proteins such as P-400 (ref. 13). This 400,000 MW protein is not detectable in the Purkinje cell axon and is therefore unlikely to be the antigen recognized by UCHT1. Prostaglandin dehydrogenase[14] and the calcium binding protein parvalbumin[15] have also been reported to be Purkinje cell-related but lack the highly restricted localization of the UCHT1-defined antigen. The intestinal peptide hormone motilin has recently been detected in Purkinje cells[16]

Table 2 Absorption experiments with UCHT1

	T lymphocyte staining	Purkinje cell staining
UCHT1 unabsorbed	+ +	+ +
UCHT1 cerebrum absorbed	+ +	+ +
UCHT1 cerebellum absorbed	±*	−

UCHT1 was diluted to 1 : 1200 (one doubling dilution below end titre) and absorbed with homogenates of rat cerebrum and cerebellum. Absorption was carried out at 20 °C for 1 h with equal volumes of diluted antibody and homogenate. Following absorption, UCHT1 binding on human T cells and Purkinje cells in frozen section was visualized by indirect immunofluorescence using a fluorescein-conjugated goat anti-mouse immunoglobulin, diluted 1 : 80.

* Weak residual staining of T cells.

but, unlike the UCHT1-defined antigen, is only present in a proportion of Purkinje cells. Furthermore, UCHT1 fails to stain motilin-containing cells of the rat duodenum. Finally, cyclic GMP-dependent protein kinase has been shown, within the rodent nervous system, to be restricted almost exclusively to Purkinje cells[17]. However, in contrast to the UCHT1 antigen, the enzyme is also present in high concentration in the muscular wall of the aorta and in various other smooth muscle cells (see Table 1).

Purkinje-specific antigens have previously been demonstrated by immunological studies with two conventional polyclonal heteroantisera. The first[18], although operationally specific, was only effective at very low titre. The second[19], raised against a glycoprotein extracted from rat cerebellum, appeared Purkinje cell-specific, but specificity was demonstrated by absorption rather than by direct testing so that small populations of antigen-containing cells elsewhere in the nervous system might have been overlooked. In addition to these studies with polyclonal antisera, a monoclonal antibody, designated CE5, reactive with Purkinje cells, has also been described[20]. CE5, unlike UCHT1, however, is relatively nonspecific, reacting with many different types of neurone including dorsal root ganglion cells and pyramidal neurones; it also labels cardiac muscle and the protozoan *Trypanosoma cruzi*. The high titre, high specificity and unlimited supply of UCHT1 and Leu-4 make them ideal immunological markers for Purkinje cells.

The work described here, together with preliminary experiments on neonatal mouse cerebellum and cerebellar mutant strains, suggests that UCHT1 and Leu-4 will become invaluable tools for studying the organization and development of cerebellar architecture and connectivity.

This work was financed by the MRC, the Imperial Cancer Research Fund, Bristol Brain Tumour Research Fund and the Francis and Augustus Newman Foundation. We thank Dr D. B. Brownell, D. Rowe, T. Gradidge and J. Singh for their help and K. Caddy for providing the data on fixatives. Monoclonal antibody 308 was donated by J. Kemshead, RFB-1 by G. Janossy and CR3/43 by D. Y. Mason. OKT3, OKT4 and OKT8 were supplied by Ortho Pharmaceuticals and Leu-4 and Leu-2a donated by Becton Dickinson.

Table 3 Reactivity of anti-haematopoietic cell monoclonal antibodies with Purkinje cells

Monoclonal antibody	Haematopoietic cell reactivity	Purkinje cell staining
UCHT1	Pan T cell	+
Leu-4	Pan T cell	+
OKT3	Pan T cell	−
OKT4	Helper T cells	−
OKT8*	Suppressor/cytotoxic T cells	−
UCHT2	Pan T cell + B.CLL	−
UCHT3	Pan T cell + B.CLL	−
CR3/43	Anti HLA-Dr	−
Leu-2a	Suppressor/cytotoxic T cells	−
2D1	All leukocytes	−
TG1	Granulocytes	−
308	Granulocytes	−
RFB-1	Lymphoid stem cells	−

* OKT8 has recently been shown to exhibit anti-ovine oligodendrocyte cross-reactivity *in vitro*[21]. However, we have been unable to demonstrate OKT8 immunostaining of oligodendrocytes in frozen sections of human white matter, optic nerve, multiple sclerosis plaques or oligodendroglioma.

Germinal centre B cells: antigen specificity and changes in heavy chain class expression

G. Kraal, I. L. Weissman & E. C. Butcher

Laboratory of Experimental Oncology, Department of Pathology,
Stanford University Medical Centre, Stanford,
California 94305, USA

Germinal centres are histologically defined aggregates of blast cells that occur in B-cell areas of lymphoid tissues after antigenic stimulation. They are believed to be associated with the development of B-cell memory and plasma cell (especially secondary, IgG and IgA) responses[1-3]. Recent studies of murine lymphoid tissues have defined cell-surface markers that distinguish germinal centre B cells from other mature B cells[4-7], permitting their identification and characterization in cell suspensions. Here we have used these markers to define and study germinal centre cells in lymph nodes, and have found that they constitute a unique population of B cells which (1) arises in response to antigenic stimulation, (2) contains nearly all of the demonstrably antigen-specific B cells in the stimulated organ, (3) bears surface IgM after primary stimulation and (4) as a population, demonstrates isotype switching to a predominant surface IgG phenotype after secondary stimulation with specific antigen. These findings demonstrate that germinal centres are a major site of proliferation and differentiation of antigen-specific B cells *in vivo*, and suggest that the germinal centre microenvironment may have an important role in heavy chain class switching during B-cell responses.

Germinal centre B cells possess unique cell-surface features. One of the most important of these is defined by peanut agglutinin (PNA)[4-7], a plant lectin with specificity for terminal galactosyl residues. In antigen-stimulated lymphoid organs, fluorescence-labelled PNA defines a discrete population of lymphocytes (termed PNA$^{\text{hi}}$) that bind 10–30 times as much PNA as the major population of lymphocytes[7] (PNA$^{\text{lo}}$). Immunohistological[4,5,7], electron microscopic[5] and cell suspension[4-7] studies of mouse Peyer's patches and stimulated lymph nodes have shown that the B cells in the PNA$^{\text{hi}}$ population are almost exclusively germinal centre lymphocytes. B cells

0028-0836/82/290377—03$01.00

outside germinal centres, as well as plasma cells and most T cells, bind only low levels of PNA[5,7]. A small proportion of T cells may also be PNA^{hi} (refs 7, 8). A secondary independent marker is IgD: immunohistological[9,10] and flow cytofluorometric[7] studies have shown that germinal centre lymphoid cells lack surface IgD, whereas essentially all other mature B cells are IgD$^+$ (ref. 7). Thus, germinal centre B cells can be identified confidently in cell suspensions of lymph nodes and Peyer's patches by virtue of their unique PNA^{hi}, IgD$^-$, Thy-1$^-$ phenotype.

BALB/c or BALB.B mice were immunized in the front foot pads with heterologous erythrocytes, and cell suspensions were made from brachial and axillary lymph nodes during or near the peak of germinal centre responses (6 days after primary or secondary immunization). Several studies were carried out to confirm the usefulness of PNA in identifying germinal centre lymphoid cells in these lymph nodes. Fluorescence activated cell sorter (FACS) analyses demonstrated the appearance of a discrete population of PNA^{hi} cells in the stimulated nodes, constituting up to 10–12% of the lymph node cells (and up to 20–30% of B cells) 6 days after primary immunization (see Fig. 1). Double fluorescence microscopy of frozen sections of stimulated nodes stained with tetramethylrhodamine isothiocyanate (TRITC)-conjugated PNA and counterstained with fluorescein-isothiocyanate (FITC)–rabbit anti-mouse Ig confirmed the remarkable specificity, within the B-cell lineage in this organ, of intense PNA staining for germinal centre cells (not shown, see Raedler *et al.*[5] for similar findings). Staining of FACS-separated PNA^{hi} and PNA^{lo} populations confirmed the observation, previously based on immunohistological studies[5,7], that plasma cells and plasmablasts are PNA^{lo} (see Fig. 1 legend).

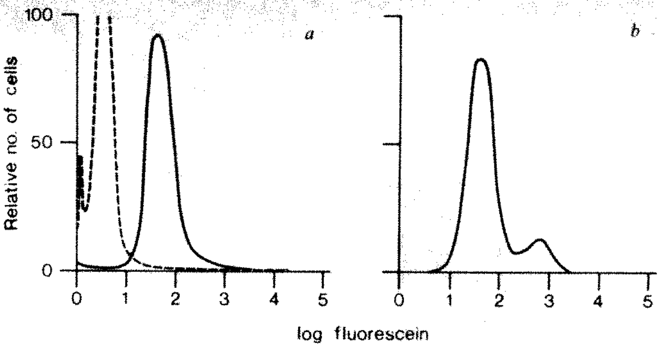

Fig. 1 Axillary and brachial lymph node cells from BALB/c mice were incubated for 5 min in an excess of FITC-conjugated PNA (EY Laboratories) at 100 μg ml^{-1} in phosphate-buffered saline, washed, and analysed on the FACS (Becton Dickinson). *a*, Unstimulated lymph node cells were stained with FITC–PNA in the presence (dotted line) or absence (solid line) of 0.2 M galactose. Most lymphocytes bind low levels of PNA to galactose-inhibitable sites, and are therefore referred to as PNA^{lo}. *b*, Six days after footpad immunizations with 1–2 × 10^7 SRBC, a discrete population of PNA^{hi} cells has arisen which binds about 20 times as much PNA as the PNA^{lo} lymphocytes. To determine if this PNA^{hi} population included significant numbers of plasma cells or plasmablasts, cytocentrifuge preparations of FACS-sorted PNA^{hi} and PNA^{lo} populations were air-dried, fixed 10 min in cold acetone, counterstained with rabbit anti-mouse immunoglobulin and examined by fluorescence microscopy. Cells containing cytoplasmic immunoglobulin segregated predominantly with the PNA^{lo} population. Of 400 sorted PNA^{lo} cells counted, 41 contained detectable internal immunoglobulin; 27 of these were mature plasma cells with eccentric nuclei, and the remaining 14 had the appearance of plasmablasts. Of 1,000 PNA^{hi} sorted cells examined, only one apparent plasma cell and seven plasmablasts were identified.

Table 1 The phenotype of PNA^{hi} sample cells in lymph nodes after immunization

	% Of cells stained	
Antibody directed against	Primary response	Secondary response
B cells (B220)	94	83
Total immunoglobulin	84	80
IgM	62	25
IgG	9	60
IgG + γ blockade	ND	1
IgG + α and μ blockade	ND	64
IgA	4	3
IgD	1	1
T cells (Thy-1 + Lyt-1)	9	10
Rabbit anti-KLH	0	1
RA3-2C1	0	0

BALB.B mice, 6–8 weeks of age, were injected with 1–2 × 10^7 SRBC in the front footpads. For analysis of the primary response, axillary and brachial lymph nodes were removed 6 days after immunization. For the secondary response lymph nodes were collected 6 days after a second injection of antigen with a 2-week interval between first and second injection. Cells were stained at a density of 10^6 cells per 10 μl of antiserum at saturating concentrations for 5–10 min and washed between first and second stages by centrifugation through serum. After incubating the cells in the second stage for 5 min, an equal volume of TRITC-conjugated PNA (EY Laboratories) at 100 μg ml^{-1} was added for another 3–4 min. The cells were then directly suspended in 1–2 ml of 2% formalin in phosphate-buffered saline washed through serum and examined microscopically. Affinity-purified anti-mouse total immunoglobulin, anti-keyhole limpet haemocyanin (KLH), and μ-chain-specific[16] and α-chain specific[7] antibodies (gifts from Drs C. Nottenburg and R. L. Coffman) and an Fab preparation of an anti-γ-serum[17] (a gift of Dr E. Vitetta) were produced in rabbits and used in combination with a fluoresceinated sheep anti-rabbit immunoglobulin second stage (Institut Pasteur, Paris). To detect δ chains a biotinylated monoclonal anti-Igh-5a, H10.4.22[18], was used in combination with fluoresceinated avidin (EY Laboratories). B cells were detected by a newly developed monoclonal rat antibody (RA3-6B2, a gift of Dr R. L. Coffman) specific for B220, the B-lineage-specific form of the T200 family of molecules[13]. A mixture of monoclonal anti-Lyt-1 (53-7.3) and anti-Thy-1 (30-H12)[19] was used to detect T cells with a highly specific fluoresceinated rabbit anti-rat immunoglobulin second stage. A monoclonal rat antibody (RA3-2Cl) with no known specificity was used as a control. The specificity of the rabbit anti-mouse γ chain reagent was tested by attempting to block staining either with a pool of IgG myeloma proteins or with a mixture of IgA and IgM myeloma proteins. Preincubation of the antiserum for 15 min with mouse IgGs totally inhibited staining but an excess of IgA (TEPC 15) and IgM myeloma proteins had no effect. 150–200 PNA^{hi} cells (with the characteristic large size and/or irregular outline of germinal centre cells) were scored, single-blind, using a Zeiss fluorescence microscope with exciter/barrier filter combinations for rhodamine and fluorescein. The data are pooled from two experiments with similar results and are expressed as the % of sample cells staining.

For studies of the surface phenotype of the PNA^{hi} population, cells were labelled with TRITC-conjugated PNA and counterstained with various (fluorescein-detected) monoclonal antibodies or heterologous antisera. Putative germinal centre cells were identified microscopically by their intense staining with PNA in combination with their characteristic larger size and frequently irregular cell outline. These criteria excluded most PNA^{hi} T cells, yet included nearly all B cells with the characteristic IgD$^-$ phenotype of germinal centre cells. Cells so identified were then examined under fluorescein filters for staining with immunological reagents.

Initial experiments describing the surface phenotype of germinal centre cells after primary and secondary immunizations are presented in Table 1. Only 10% of the sample PNA^{hi} population were contaminating T cells; the remainder were IgD$^-$ B cells. The results demonstrate that IgM is the predominant isotype of surface immunoglobulin during the primary response, but in a secondary response, germinal centre cells mainly express surface IgG. Although the present findings do not demonstrate that these B cells synthesize their surface immunoglobulin, we have previously presented evidence based on allelic exclusion that the comparable population of Peyer's patch germinal centre cells do synthesize their major class of surface immunoglobulin (IgA)[6,7]. (In striking contrast to the pattern of immunoglobulin expression by peripheral node germinal centre cells, 50–75% of germinal centre cells in Peyer's patches express surface IgA[7].) These findings suggest that germinal centres may have an important role in the process of isotype switching.

We wished therefore to determine if the B cells proliferating in germinal centres are specific for the immunizing antigen, as suggested by work of Sordat *et al.*[21], or if germinal centres merely represent sites of nonspecific expansion and perhaps isotype switching of all available B cells. Kanowith-Klein *et al.*[12] have shown that the proportion of antigen binding B cells bearing surface IgG increases during the immune response to heterologous erythrocytes. Thus the switch we observed from a predominance of IgM$^+$ to IgG$^+$ cells in germinal centres with restimulation with the same antigen suggested that these cells

Table 2 Heavy chain isotype switching of germinal centre cells is antigen specific

Antigen 1° Injection	 2° Injection	% Of PNA^{hi} cells with surface IgM	 IgG
SRBC	SRBC	31	48
SRBC	HuRBC	56	13
SRBC	None	46	14
HuRBC	SRBC	52	21
HuRBC	HuRBC	36	49

BALB.B mice were immunized in the front foot pads with either SRBC or HuRBC. After 3 weeks the animals were boosted with one of the two antigens. Five days later lymph node cells were prepared and stained as described in Table 1 legend. 150–200 PNA^{hi} cells were counted single-blind. The results are from a representative experiment, expressed as the percentage of PNA^{hi} sample cells staining with the antiserum.

might be antigen specific. This reasoning was greatly strengthened by the demonstration that this IgM to IgG switch was itself antigen specific. After priming with SRBC, secondary immunization with SRBC reproducibly caused a switch in the germinal centre cells to a predominance of IgG$^+$ cells, whereas secondary injection of human red cells (HuRBC) caused no shift (see Table 2). After HuRBC priming, secondary HuRBC but not SRBC injection caused the switch.

More direct evidence of antigen specificity has been obtained at the single cell level. By using rosetting techniques, we have found that almost all specific-antigen-binding B cells have the surface phenotype of germinal centre cells during the active immune response to SRBC. Suspensions of immunized lymph nodes were incubated with RBC briefly on ice, and subsequently stained with TRITC–PNA. Ten per cent of PNA^{hi}, IgD$^-$ cells in SRBC-immunized lymph nodes formed SRBC rosettes. As many SRBC antigens are probably either located on the erythrocyte surface, or not sufficiently represented to support rosette formation, this proportion of rosetting cells probably underestimates the percentage of germinal centre cells that are antigen specific. Furthermore, after removal of glass-adherent cells (presumably macrophages binding cytophilic antibody), 98% (104/106) or rosetting cells were PNA^{hi}, and 100% (100/100) stained with RA3-6B2, a monoclonal antibody against B220[13], the B-lineage specific form of the T200 family of molecules. Similar results were obtained after secondary injections.

Rosette formation was antigen-specific. Six days after foot pad injection of SRBC or HuRBC, immunized lymph node cells were incubated with a mixture of HuRBC, and FITC-labelled SRBC. As shown in Table 3, PNA^{hi} cells of SRBC recipients only rosetted with SRBC, whereas only HuRBC rosettes were formed after HuRBC immunization. To rule out the possibility that these results were simply due to cytophilic adsorption of anti-RBC antibodies, individual mice were immunized with a mixture of HuRBC and SRBC in the same footpad, and 6 days later the specificity of PNA^{hi} rosetting cells was determined. If cytophilic antibodies were involved, we could expect most rosettes to be mixed, containing both FITC–SRBC and unlabelled HuRBC. Instead, all rosettes were formed specifically with one or the other RBC type, providing strong evidence that PNA^{hi} cells form rosettes by synthesis and surface expression of specific antibody.

Table 3 Germinal centre cells form rosettes specifically with the immunizing antigen

Immunogen	HuRBC	No. of rosetting cells binding HuRBC and SRBC	SRBC
SRBC	0	0	100
HuRBC	113	0	0
SRBC and HuRBC	51	0	75

BALB.B mice were injected with SRBC, HuBRC or a 1:1 mixture of both erythrocyte types. After 6 days cell suspensions from axillary and brachial lymph nodes were prepared and incubated for 1 h at 37 °C in glass tubes to remove adherent cells. Nonadherent cells were then added to a 1:1 mixture of SRBC and HuRBC and allowed to form rosettes for 10 min at 4 °C. The cell mixtures were spun down and resuspended with rhodaminated PNA for 5 min after which they were diluted and directly examined in the fluorescence microscope. SRBC were labelled by incubation with FITC before rosette formation[20]. Rosettes were (1) first identified microscopically under dark-field illumination, (2) then examined under UV epi-illumination using the filter combination for rhodamine to determine if the rosetting cells were PNA^{hi}, and if so, (3) the type of erythrocyte in the rosette was determined using filters for fluorescein. Rosettes were scored when at least 10 erythrocytes surrounded one nucleated centre cell. Approximately 10–15% of the specific rosettes, thus defined, contained one or two heterologous contaminating erythrocytes, but the frequency was no greater in recipients of mixed erythrocytes than in animals immunized with only one type. All rosette-forming cells were B cells (100 RA3-6B2$^+$ per 100 rosettes counted); nearly all were PNA-binding (104 PNA^{hi} per 106 rosettes counted); and 10% (9.3; 10.1%) of PNA^{hi} cells formed rosettes. Similar results were obtained after secondary immunization. Truly mixed rosettes could be easily identified using this technique. In recipients immunized with both RBC types many mixed rosettes were observed before removal of adherent cells (presumably macrophages bearing cytophilically absorbed antibody).

The present findings support the concept that antigen-specific virgin B cells are recruited in the formation of germinal centres during a primary immune response, and subsequently undergo differentiation and selection in this site. Although many differentiation events may occur within the germinal centre population (for example, affinity maturation, suppression and/or reprogramming of normal lymphocyte migration mechanisms[6]), we have focused initially on changes in heavy chain class expression. If the precursors of germinal centre cells are IgD$^+$, IgM$^+$ lymphocytes (as seems likely, although other lineages cannot be ruled out[11,14]), the first such alteration in isotype expression, which may be necessary on entry into the germinal centre, is the loss of surface IgD. Occurrence and significance of IgD regulation however, remain speculative. More interesting is the direct demonstration of changes in the proportions of germinal centre cells expressing IgM and IgG during the immune response. The switch to a predominance of IgG bearing cells, and the observation that almost all antigen-specific B cells seem to be maintained in the PNA^{hi} pool, strongly argue that the genetic rearrangements leading to heavy chain class switching occur in the germinal centre. The specific lack of IgA expression in peripheral lymph node as opposed to Peyer's patch germinal centres suggests that the germinal centre microenvironment (perhaps in conjunction with T-cell influences[15]) may be capable of directing the heavy chain class switch, or perhaps of selecting cells that have randomly switched to the isotype appropriate to the site of the immune response. Although our findings support a role for germinal centres in the production of memory B cells and plasma cell precursors[1–3], a thorough understanding of the role of germinal centres in humoral immunity must await direct lineage analyses.

Studies of the murine λ1 light chains produced by myeloma cells provided the first evidence for somatic point mutation of germ-line variable (V) region genes. An examination of the variable regions of 19 λ1 chains revealed seven which differed from a common sequence by one to three amino acid substitutions[1]. Subsequently, one of these presumed somatic variants of the single λ1 V gene was characterized by DNA sequence analysis of the rearranged functional gene[2]. The predicted DNA sequence alteration was observed and no silent mutation was evident. These studies of λ chain variants suggested that the hypervariable, complementarity-determining regions (CDRs) ht be a preferred site of somatic mutation because all seven characterized variants contained substitutions only in these regions. By contrast, comparisons of closely related κ chain variable region amino acid sequences, and more recently V_κ and V_H genes[8–12], have suggested that somatic mutation probably occurs in codons for both framework and CDR residues. To examine this apparent discrepancy between the sites of somatic mutation in λ and κ genes, we have determined the nucleotide sequence of two λ1 gene from hybridomas and a λ2 gene from a myeloma. These sequences demonstrate that somatic mutation in λ genes can occur in both the framework and CDR residues.

We have previously characterized the sequences of genes for the V_H regions of two antibodies which bear (4-hydroxy-3-nitrophenyl)acetyl (NP)[b] idiotypic determinants[8]. These antibodies were from hybridomas of C57BL/6 origin and possessed λ1 light chains: one was from hybridoma B1–8 which secretes an IgM antibody whose μ chain is specified by a germ-line nucleic acid sequence; another was from the S43 hybridoma which produces an IgG2a antibody in which 10 base pairs (bp) in the V_H region were altered from the germ-line configuration by somatic point mutations. We determined, therefore, whether somatic mutation in the λ1 light chains paralleled that observed in their associated V_H regions.

In addition, we have determined the nucleotide sequence of pλ2–1, the λ2 cDNA clone derived from MOPC-315[13]. A comparison of the amino acid sequence of this protein with the sequence predicted from the germ-line λ2 V gene indicated the presence of somatic mutation[14], which was further defined by determining the nucleotide sequence encoding this protein.

Molecular cDNA clones of the λ1 light chain mRNAs were constructed as previously described[8] using the DNA insert from pABλ1–1 as probe[13]. A preliminary characterization of several λ1-containing cDNA clones by restriction enzyme cleavage suggested the presence of somatic mutation in the S43-derived sequence. Restriction enzyme digests of three B1–8 clones were consistent with the sites predicted from the germ-line λ1 DNA sequence[2,13] but the S43-derived clone, pABλ1–15, had an additional *Kpn*I site in the J region (Fig. 1).

To precisely identify differences from the germ-line sequence, the longest cDNA clones pABλ1–9 (B1–8) and pABλ1–15 (S43), were sequenced. The sequence of the pABλ1–9 insert indicated that the clone began with codon 47 and extended in the 3′ direction through the poly(A) (Fig. 1). This nucleotide sequence was identical to that found in the BALB/c germ line. Peptide mapping of the B1–8 λ1 chain also suggested that this chain contained the germ line-encoded sequence (T.I., unpublished).

The DNA sequence of the longest S43-derived clone, pABλ1–15, encoding the leader, V, J and most of the C region (up to the *Pvu*II site at codon 195) is presented in Fig. 2. (The rest of the λ1 sequence in Fig. 2 was derived from pABλ1–9.) The S43 V-region sequence contained three somatic mutations when compared with the germ-line sequence; two in the $V_{\lambda 1}$ region at codons 80 and 87 and one in the J segment at codon 103. Otherwise the DNA sequence consisting of the leader, V, J and the available C region was exactly the same as that found in the B1–8-derived clone, pABλ1–9, or in the BALB/c λ germ-line DNA sequences[13]. The somatic mutations in the λ chain of S43 all occurred outside the CDRs—they are the first somatic mutations to be located outside these regions in a productive λ1 gene. The mutations in codons 80 and 87 result in fairly conservative amino acid replacements; the new methionine (Met) residue at codon 87 is also found at that position in the λ2 V region.

Comparison of the C57BL/6 and BALB/c λ1 germ-line cDNA sequences beginning with the initiator Met codon and extending 3′ to the poly(A) sequence showed complete identity. Given the polymorphisms evident in comparisons of heavy chain constant regions between these two strains[15], the complete absence of polymorphic differences in these λ1 sequences is notable.

To characterize somatic mutations present in the MOPC-315 λ2 chain, the DNA sequence of pλ – 1 was determined[13] (Fig. 2). Six somatic mutations in the V region were found, at codons 38, 50, 94, 95 and 96. This sequence corrects the published amino acid sequence at positions 55 (where MOPC-315 λ2 has the germ-line sequence), and at 145 and 146 and it removes the ambiguity at codons 147–148[16,17]. All of the observed somatic mutations occurred in CDRs except for those found in codon 38. The precise junction between the $V_{\lambda 2}$ and $J_{\lambda 2}$ segments can be defined because the $J_{\lambda 2}$ germ-line sequence has recently been determined[18,19]. The $J_{\lambda 2}$ sequence in pλ2–1 is identical to the germ-line sequence.

These analyses have shown that somatic mutations in λ chains need not be localized in the CDRs. The sequence of an aberrantly rearranged λ1 gene in MOPC-315 also showed somatic variation outside of the CDRs[20]. It therefore seems likely that for λ, as for κ[3–7] and V_H genes[8–12], somatic mutation occurs throughout the variable region sequence.

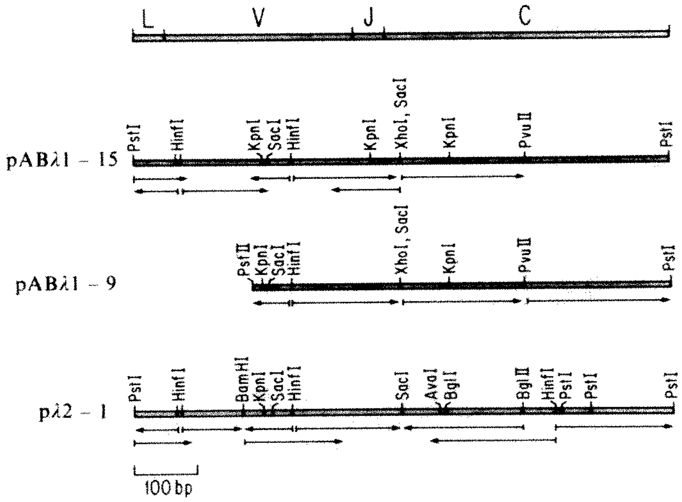

Fig. 1 Restriction map and DNA sequencing of λ cDNA clones. The clone pABλ1–15 was derived from the S43 hybridoma, pABλ1–9 from B1–8 and pλ2–1 from the MOPC–315 myeloma[13]. The DNA sequence was determined using the Maxam–Gilbert[25] procedure on 5′-kinased DNA. The arrows indicate the DNA sequences determined in the 5′ to 3′ direction.

Fig. 2 Nucleotide sequence of λ cDNA clones. The DNA sequence labelled λ1–S43 was derived from the pABλ1–15 (codons −19 to 195) and pABλ1–9 (codon 196 to the poly(A) sequence) plasmids and the λ2–MOPC-315 sequence was derived from the pλ2-1 plasmid[13] (Fig. 1). The predicted amino acid sequence is indicated above the nucleotide sequence and these residues are numbered. A dash (—) indicates a position where the λ2 sequence is identical to the λ1 sequence, and a period (.) indicates a gap used for sequence comparison at codon 173. The circled nucleotides immediately above the λ1 sequence at codons 80, 87 and 103 and immediately below the λ2 sequence at codons 38, 50, 94, 95 and 96 indicate the sequences of the corresponding germ-line genes: the λ1 and λ2 V and J germ-line sequences were determined by Tonegawa and co-workers[2,14,18]. The V, J and C region boundaries are indicated; arrows indicate the location of the V–J junction. The double arrow above the λ1 sequence indicates two possible sites for the actual junction. The arrow beneath the λ2 sequence indicates that there is no ambiguity in the assignment for the λ2 chain. The 3′ untranslated regions are numbered separately to facilitate reference to that region. One sequence error found in our previous sequence[13] is corrected here (the 3′-terminal λ1 sequence immediately preceding the poly(A) in BALB/c and C57BL/6 is AC and not ATC). All of these sequences were determined using the Maxam–Gilbert methods[25]. Restriction enzyme sites in the λ2 clone occur at the following codon positions: *Ava*I, 144; *Bam*HI, 38; *Bgl*I, 150; *Bgl*II, 189; *Hinf*I, 5, 7, 63 and 208; *Kpn*I, 52; *Pst*I, 212 (base pair position 31 in 3′ UT region); and *Sac*I, 57, 127. The inserted λ2 sequence at the *Pst*I site in the cloning vector is CTGCAG$_{20}$–insert–A$_{23}$–C$_{16}$ TGCAG. The corresponding sequence in pABλ1–15 is CTGCAG$_{13}$ CG$_6$–insert and in pABλ1–9, insert–A$_{26}$C$_{12}$ TGCAG.

In previous experiments, all of the observed somatic variation in myeloma $\lambda 1$ chains was restricted to the CDRs[1]. Furthermore, the existing data on V_κ and V_H shows a strong bias for somatic variation (as well as genetic variation) to occur in the CDRs (refs 8, 12 and A.B., M.P. & D.B., unpublished). There are two alternative possibilities for this clustering of somatic events: either there could be a predisposition for mutations in the CDRs, or selection could be operating. Preferential somatic mutation in the CDRs would require a remarkably specific mechanism but may occur. Selection could either act negatively, causing a loss of variants in the framework regions, or could act positively and favour proteins with variation in the CDRs. Negative selection seems unlikely because an excess of silent (synonymous) mutations in the framework compared to those from random mutational events would be expected. However the ratio between silent and replacement mutations in these λ sequences was approximately that expected from random mutation (25%): S43 and the MOPC-315 $\lambda 2$ had 1/3 and 1/6 silent mutations, respectively. Positive selection could be exerted either through better antigen binding due to variations in the CDRs or selective regulation by the immune system, but the expected bias in favour of replacement mutations might not be evident in the limited data available.

The constant regions of both the $\lambda 1$ light chain and $\gamma 2a$ heavy chain[15] of the S43 hybridoma are germ-line DNA sequences although both variable regions show mutation[8]. Studies of the spread of somatic mutation away from the coding sequence suggest that barriers must exist to the spread of mutational activity. For κ light chains, no spread outside of the coding regions was observed[5-7] although for $\lambda 1$, mutations just 3′ to the J segments have been observed[2,20]. Because the $V_{\lambda 1}$ gene is only 1,250 nucleotides from the $C_{\lambda 1}$ gene in the joined configuration[2], the lack of mutation in the S43$C_{\lambda 1}$ region suggests that the barrier to mutational spread in the $\lambda 1$ gene is within the 1,250 nucleotides 5′ to the $C_{\lambda 1}$ region. For heavy chains, extensive spread of mutation away from the rearranged V_H region has been observed[9,10].

There does not seem to be absolute specificity for mutations at particular nucleotides although similarities have been observed[21]. Interestingly, the three S43 $\lambda 1$ chain mutations occurred only at purine residues and we have noted a similar bias in the V_H region from the S43 hybridoma (9 out of 10)[8]. The six somatic mutations in the $\lambda 2$ cDNA, however, occurred at all four bases, three at purine and three at pyrimidine residues. The significance of a purine bias in some but not all data remains puzzling.

The MOPC-315 tumour expresses two λ mRNA species, one producing a normal $\lambda 2$ protein and the other producing a truncated $\lambda 1$ protein[13]. The V–J junction of the $\lambda 1$ sequence puts the reading of the rest of the mRNA out of frame[20]. Presumably in the progenitor MOPC-315 cell, the $\lambda 1$ gene rearranged first but because a functional polypeptide could not be synthesized, the $\lambda 2$ gene was later rearranged. Following the productive $\lambda 2$ rearrangement, a similar level of somatic mutation occurred in both rearranged λ genes, the $\lambda 1$ gene having seven somatic mutations in its coding sequence[20] and the $\lambda 2$ containing six mutated bases (Fig. 2). Pech *et al.*[5] found a related situation for κ genes where in one myeloma cell both an expressed and an unexpressed but rearranged κ gene showed similar levels of somatic variation.

Except for one report (HPC 16; ref. 22), data on somatic variation has revealed no variants appearing in association with the μ heavy chain isotype but many variants have occurred in association with other isotypes[8,23]. This again was seen in the λ data: B1-8 has a μ heavy chain and no somatic variation in its λ chain, S43 has a $\gamma 2a$ heavy chain and somatic variation in both its heavy and λ light chain, and MOPC-315, with an α heavy chain, has somatic variation in its $\lambda 2$ light chain. Somatic mutation is not, however, obligatory during isotype switching: protein sequencing has identified germ-line sequences in non-IgM antibodies[23] as has nucleotide sequencing (A.B., M.P. & D.B., in preparation). It seems that isotype switching may precede somatic mutation. Somatic mutation may be an inducible phenomenon (perhaps via T-cell help) in some stage of B-cell development after its encounter with antigen. More data will be needed to clarify these relationships.

Finally, these data allow a direct comparison of the nucleotide sequences of the $\lambda 1$ and $\lambda 2$ constant regions. The two genes are obviously related but differ at 30 out of 105 amino acids (Fig. 2). They are more different from one another than the three human λ sequences recently determined[24]. They differ so extensively in their 3′ flanking sequences that the homology is not very evident (and therefore in Fig. 2 the identities are not shown with dashes). The two genes probably diverged in a species ancestral to the present mouse species. By contrast, the human λ genes are closely related and therefore diverged quite recently, as did the mouse $\lambda 2$ and $\lambda 3$ genes as shown by protein sequence data[17].

This work was supported by grants from the American Cancer Society and the NCI and a contribution from the Whitehead Charitable Foundation. A.B. was a postdoctoral fellow of the Medical Foundation. D.B. is an American Cancer Society Research Professor.

Mapping class I gene sequences in the major histocompatibility complex

Larry R. Pease, Stanley G. Nathenson & Leslie A. Leinwand

Department of Microbiology and Immunology and Department
of Cell Biology, Albert Einstein College of Medicine, Bronx,
New York 10461, USA

The class I glycoproteins of the major histocompatibility complex (MHC) are products of closely linked genes on the 17th chromosome of the mouse. Four highly homologous cell surface proteins, K, D, L, and Qa-2 (refs 1–4), belonging to this multigene family have been analysed. Several additional members[5–7], M, R, TL, are indicated by biochemical data and recent serological data suggest the family is larger[8]. Recent reports using recombinant DNA technology suggest that the class I system is an extensive multigene family[9–12]. In this report we describe results of experiments using restriction enzyme digestion of DNA from a group of standard, congeneic and MHC

0028-0836/82/290382—04$01.00

recombinant mouse strains followed by hybridization to H–2 cDNA probes. Particular bands of hybridization can be assigned to specific H–2 haplotypes and, therefore, to the MHC region of the 17th chromosome. A number of the MHC polymorphic bands have been assigned to genetic map positions in the K and D-L regions of the H–2 complex. Additional class I gene sequences map outside the boundaries of the traditional H–2 complex (K, I, S, D), into the Qa-T1a region. At least one sequence is centromeric to the K locus. Further, amino terminal and carboxy terminal probes show different restriction patterns, suggesting that the exons corresponding to the different domains of the class I glycoproteins may have different evolutionary histories.

We used two cDNA probes[9] to identify the DNA sequences bearing homology to the class I antigens. The first, pH-2.IIa, is homologous to the exons encoding from amino acid 167 through the carboxy terminus of the H–2K^{b} glycoprotein. The second probe, pH-2.III, is homologous to exons encoding from amino acid 63 to 160.

To determine whether the bands that hybridize to the cDNA probes are specific for any given haplotype and if these bands are located in the MHC, comparisons were made between hybridization patterns of class I cDNAS to genomic DNAs of standard mouse strains and those bearing (1) different MHC haplotypes but identical non-MHC backgrounds, and (2) identical MHC haplotypes but different non-MHC backgrounds. DNA from these standard and congeneic mouse strains was digested with *Bam*HI endonuclease and examined by hybridization to the carboxy terminal cDNA probe pH-IIa (Fig. 1*a*). The results show that approximately 50% of the bands in the DNA of each haplotype are polymorphic when compared with the other haplotypes (7/13 in the *b* haplotype, 9/16 in the *d* haplotype, 6/13 in the *k* haplotype). This polymorphism can be assigned to the MHC segment on the 17th chromosome because the congenic strains, BALB · B, BALB/c and BALB · K differ only at the MHC chromosomal segment. Schematic representation of the banding patterns and the distribution among three haplotypes is shown in Fig. 2. The degree of polymorphism observed by our analyses (approximately 50%) is probably an underestimate since dissimilar bands may be approximately equal in size and high molecular weight bands greater than 5 kilobases (kb) are not resolved as well as the smaller bands.

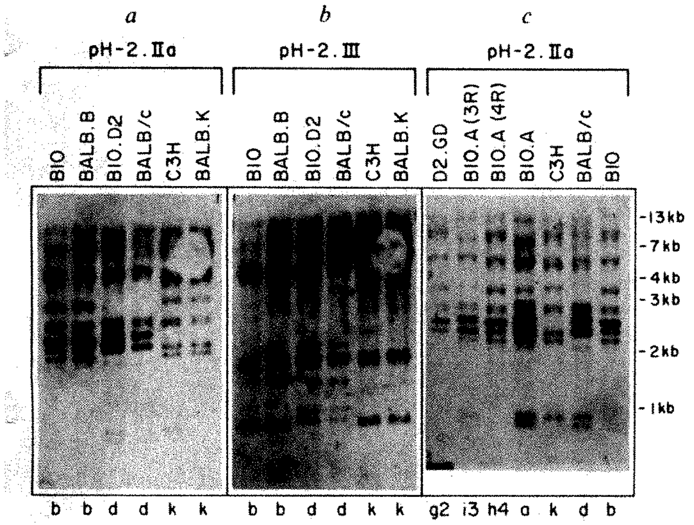

Fig. 1 Characterization of *Bam*HI genomic restriction fragments by hybridization to the cDNA probes, pH-2.IIa and pH-2.III. Splenic DNA was isolated from inbred strains maintained by Dr F. Lilly. Spleen cells were disrupted in 10 mM Tris (*p*H 7.4), 0.05 M EDTA, 0.5%SDS and 100 g ml^{-1} protinease K and incubated at 37 °C for 16 h. Protein contaminants were extracted from high molecular weight DNAs with phenol, chloroform, isoamyl alcohol, and the DNAs were recovered by ethanol precipitation. Samples of 12 μg of DNA from each strain were digested to completion with *Bam*HI and electrophoresed overnight on 0.8% Agarose gels in G-M buffer (0.18 M Tris, 0.18 M boric acid, 6 mM EDTA, *p*H 8.3) at 60 V. The DNA in the gels was transferred to nitrocellulose paper by the method of Southern[13]. Following transfer, the filters were prehybridized (5 × SSC, 50 mM PO$_4$, *p*H 7.4, 50 μg ml^{-1} salmon sperm DNA, 50 μg ml^{-1} poly(A), 1X Denhardts solution) at 65 °C for 6 h. Radioactively labelled cDNA clones (2×10^5 c.p.m. ml^{-1}) were added to prehybridization solution containing 20% dextran sulphate. After hybridizing for 6 h at 65 °C the filters were washed three times in 2 × SSC, 0.2% SDS at 65 °C and twice in 0.1 × SSC, 0.2% SDS at 55 °C for 20 min. The filters were exposed to X-ray film with an intensifying screen at −70 °C.

The distribution of *Bam*HI fragments homologous to the two probes was different (Fig 1*a*,*b*). Unlike the pattern of bands observed with the carboxy terminal probe H-2.IIa, the amino terminal probe, pH-2.III, distinguished between two groups of bands. One family consisted of four prominent bands which hybridized strongly to the probe while the remaining 7 to 9 bands hybridized weakly.

The availability of congeneic mouse strains as well as recombinant mouse strains, that were derived from previously defined arrays of class I alleles, provided the means to assign the class I hybridizing bands not only to the MHC of chromosome 17 but also to specific map positions within the MHC. The results of a series of experiments (as in Fig. 1*c*) utilizing *b*, *d*, and *k* haplotypes and recombinant haplotypes, *a*, *h4*, *i3*, *i5*, *g2* and *g* are shown in Fig. 3. The mapping patterns fall into several groups. Bands 1, 3, 4, 5, 6, 7 and 17 cannot be mapped to any specific region within the MHC since these segments of the genome do not contain detectably polymorphic *Bam*HI sites. Two *Bam*HI bands, 2 and 18, map to the K end of the H–2 complex. Band 2 is present in the *d* haplotype, also present in th *g2* and *g* haplotypes, but absent in the *b* haplotype. Since *g2* and *g* are haplotypes derived from recombination events that substituted a portion of the *b* haplotype at the D end of the H–2 complex, band 2 must map to the region containing the alleles derived from the *d* haplotype, namely the K end. Band 18 can also be mapped to the K end since it is present in the *b* haplotype but is absent in the *d*, *g2* and *g* haplotypes.

Another group of bands appears to map to the D end of the H–2 complex. Band 12, for example, is present in the *d* and *a* haplotypes but not in the *b* haplotype. Recombinants *i3* and *i5* contain band 12 and have *a* haplotype-specific genetic sequence from I–C through the T1a region. Thus the presence of band 12 in these strains indicates that the location of the DNA fragments contained in band 12 must be at the D end. The absence of band 12 from the recombinant *h4* which does not have either the *d* or *a* haplotype sequences in the D region further supports this mapping assignment. Similar analyses can be used for the mapping of the other bands, 10, 11, 13, 14, 16, 20 and 22 to the D end.

The remaining bands, 8, 9, 15, 19 and 21 cannot be directly mapped by the recombinants tested. The ambiguity about the location of these bands arises because the genetic regions homologous to class I cDNA probes may map to the centromeric as well as the distal side of the MHC because the boundaries defined by the congeneic and recombinant strains have not been established. However, it is possible to eliminate some regions of the MHC, where these bands cannot be located. For example, bands 15 and 19 which are present in the *a* haplotype but not the *k* haplotype must be absent from the K or I–A region of the H–2 complex. Similarly, bands 8 and 21, which are present in the *k* haplotype but in none of the other strains examined, should not be present in the K or Ia region. Band 9 is present in the *a* haplotype but absent from both *d* and *k* haplotypes and thus must map outside of the traditionally defined H–2 complex since the *a* haplotype contains both *d* and *k* alleles throughout the complex.

The genetic sequences mapping to the D-end of the H–2 complex have been analysed with additional restriction enzymes and a Qa-T1a congeneic mouse line, B6.T1a^{a} (data not shown). The recombinant MHC haplotype of this inbred strain includes the K, D and L alleles of the *b* haplotype and the Qa-T1a

Fig. 2 Schematic representation of *Bam*HI fragments hybridizing to the carboxy terminal probe pH-2.IIa. This summary is based on several analyses, including those shown in Fig. 1. Bands were assigned a number according to their relative migratory position on 0.8% agarose gels in G-M buffer (see Fig. 1). Bands not distinguishably different among haplotypes were assigned the same number. Size estimates are based on band mobility relative to *Hind*-III fragments of λ phage DNA.

alleles of the *a* haplotype. A comparison of the banding patterns of B6.T1a^a with those from the strains B10(H-2^b), B10.A (H-2^a), and B10.A(3R) (H-2^{i3}) (Fig. 3), subdivides the polymorphic D-end sequences into two groups, those mapping to the D-L region and those mapping to the Qa-T1a region. Similar mapping assignments of Class I genes to the Qa-T1a region have been reported by others[11,12].

A similar analysis has been carried out using the amino terminal probe pH-2.III (data not shown). Results are similar to the pattern seen with pH-2.IIa with the exceptions that two instead of one *d* haplotype specific fragment maps to the K end, and one fragment shared by the *d* and *a* haplotypes maps between H-2K and the centromere.

The different hybridization patterns observed with the amino terminal and carboxy terminal probes for the *Bam*HI fragments (Fig. 1), raise questions about the evolutionary relationships among the exons representing the protein domains of the class I antigens. For example, recent evidence suggests that the third protein domain of H-2K^b, (approximately amino acids 180 to 270), is critical for association with β_2-microglobulin (K. Yokoyama and S.G.N., unpublished data). This region is quite important for the function of the molecule. Since other class I glycoproteins are believed to associate with β_2-microglobulin[15], they may also retain a similarly conserved domain. This domain is homologous to the carboxy terminal probe (pH-2.IIa), but not to the amino terminal probe, a relationship which could be

Fig. 3 Summary of H-2 recombinant *Bam*HI banding patterns. As described in Fig. 1, DNAs from the inbred strains B10, BALB/c, and C3H were compared with the DNA from the presumed B10.A, the *a*×*b* haplotype recombinants B10.A(3R), B10.A(4R), B10.A(5R), and the *b*×*d* haplotype recombinants D2.GD and BALB.G. The approximate positions of recombinant sites, marked with a bar, in all recombinant strains have been established by classical mapping using serological markers[14]. The presence or absence of different pH-2.IIa homologous *Bam*HI bands, as defined in Fig. 2, are shown (blank versus filled space) next to each strain examined. Unique bands resulting from recombination were not observed. The relative position of bands on the 17th chromosome is presented schematically.

responsible for the extensive strong cross-hybridization of the probe with numerous class I sequences throughout the MHC. In contrast, the amino terminal probe hybridized to restriction fragments, with various intensities, suggesting that those sequences homologous to the amino terminal portion of the molecules have evolved more rapidly than those homologous to the C-terminal portion.

The findings reported in this study indicate that a multigene family, homologous to genes encoding class I H-2 antigens, extends from the centromeric side of the K region through the Qa-Tla region on chromosome 17. Most of the polymorphic bands map the gene sequences distal, with respect to the centromere, to the complement components (S region) of the H-2 complex. Many of these sequences clearly are associated with the Qa and Tla regions. These data suggest that the H-2 complex is only a small part of a larger set of genes comprising the major histocompatibility complex.

Reactivation of latent feline leukaemia virus infection

Jennifer L. Rojko*, Edward A. Hoover*†, Sandra L. Quackenbush* & Richard G. Olsen*†‡

* Department of Veterinary Pathobiology, † Comprehensive Cancer Center and ‡ Department of Microbiology, The Ohio State University, 484 W. 12th Avenue, Columbus, Ohio 43210, USA

In most cats exposed to the contagious[1] feline leukemia virus (FeLV), viral replication is contained in target haematopoietic tissues[2] and elicits humoral immunity to FeLV and to the feline oncornavirus-associated cell membrane antigen (FOCMA)[3–6]. Recently, we and others have considered that these ostensibly self-limiting infections might be persistent nonproductive (latent) infections in certain haematopoietic cells. This hypothesis could account for the relapsing viraemias[7], protracted incubation periods[8], persistently high titres of antiviral and anti-FOCMA antibodies[8], appearance of FeLV p27 antigen in serum of otherwise non-viraemic animals[9] and occurrence of FeLV-negative but FOCMA-positive leukaemias in naturally infected pet cats[10,11]. Here we describe the reactivation of latent FeLV from myelomonocytic and lymphoid cells of cats immune to FeLV, cats bearing FeLV-negative tumours, and kittens congenitally exposed to FeLV. Furthermore, the reappearance of FeLV infection is suppressed by the host's immune system but this can be altered by adrenal corticosteroid hormones *in vivo* and *in vitro*.

Self-limiting (regressive) FeLV infection was established in 10 adult specific pathogen-free cats by two oral-nasal exposures to 10^5 focus-forming units (FFU) of FeLV-R (Rickard) strain[12] and confirmed by demonstration of transient group specific antigen (GSA) in peripheral blood mononuclear leukocytes (PBML)[2,13], 1–3 weeks after exposure and persistent FOCMA-L[5,6,14] and FOCMA-S[14] antibody responses 2–4 weeks after exposure.

At 16–20 weeks after exposure, femoral bone marrow cells, mesenteric lymph node cells, peritoneal macrophages and PBML were collected. Freshly isolated cells were negative for GSA by fixed-cell immunofluorescence assay[13] and were negative for replicating FeLV by a viral infectivity assay[15] (Table 1). However, high titres of FeLV were reactivated following isolation and *in vitro* propagation of marrow from 8 of 10 FeLV-immune cats but not from any of 4 FeLV-naive cats (Table 1). Identification of the reactivated agent from four cats as FeLV was confirmed by neutralization[16] of its infectivity for clone 81 cells. This was achieved by preincubation with a 1:10 dilution of goat anti-FeLV serum or a 1:4 dilution of autochthonous cat anti-FeLV serum but not FeLV-naive goat or cat serum. Moreover, immunofluorescent examination of methanol-fixed, cytocentrifuged preparations of marrow cells demonstrated small clusters of GSA-positive proliferating myelomonocytic precursor cells (20% of total cells present). Neither the differentiated macrophage majority nor the mature granulocyte minority also present contained GSA. Refractoriness to retroviral replication, therefore, accompanies differentiation of feline myelomonocytic progenitor cells.

Stimulation of lymphocytes from lymph node but not bone arrow, by the feline T_γ cell mitogen staphylococcal Protein A (Protein A)[17] gave rise to low titres of recrudescent FeLV. Unstimulated nodal cells and PBML did not generate viral infectivity, nor was it found in cells activated by other T cell mitogens (phytohaemagglutinin, pokeweed mitogen, concanavalin A) or the B cell mitogen lipopolysaccharide[18]. Lymphocyte and macrophage growth factors and the tumour promotor, 12-*O*-tetradecanoyl-phorbol-acetate, also failed to reactivate GSA or viral infectivity in node cells or PBML. Thioglycollate-induced peritoneal macrophages did not reactivate GSA or viral infectivity (Table 1). Parallel cultures of marrow, lymphocytes and macrophages from FeLV-naive cats were negative (Table 1; ref. 19).

Bone marrow, tumour biopsies, PBML and serum were obtained from two pet cats referred to Ohio State University Veterinary Teaching Hospital for FeLV-negative lymphosarcoma of the mesenteric or popliteal lymph nodes (Table 1). In both cats, virus was reactivated from cultured marrow cells but not blood or tumour cells.

Finally, matings between two regressor females (cats 748B1, 1586) and two regressor males (cats 1604, 748B2) produced two litters of five kittens (kittens 1586-1, 2, 3; 748B1-1, 2) with evidence of congenital FeLV infections (Table 1). Both females were re-exposed by a single intraperitoneal dose of FeLV during the first week of gestation but remained negative for viraemia of marrow origin[2,13] throughout the 9-week gestation period. Freshly isolated fetal (1586-1, 45 days gestation) and neonatal (1586-2, 3; 748B1-1, 2) lymph node, thymus and maternal placenta (1586) were negative for GSA and viral infectivity. Infectious virus was expressed in cultured marrow from three kittens (1586-1, 2; 748B1-1), cultured thymus of two kittens (1586-1; 748B1-1) and freshly isolated, as well as cultured, liver haematopoietic cells of the fetal kitten (1586-1).

The presence of FeLV replication in fetal haematopoietic cells, but not maternal placenta, suggested that transplacental passage of FeLV was not prevented by maternal anti-FeLV responses. Other workers have shown that in cats the majority of maternal antibody was transferred in colostrum[20–22]. Passive (colostral) transfer of maternal FeLV-neutralizing antibody[23] to suckling neonates is perhaps responsible for maintenance of the neonatal infection in its non-productive, but reactivatable, form.

Therefore, latent FeLV infections are characterized by absence of infectious virus in freshly isolated marrow, node, macrophage and PBML, and reactivation of viral infectivity

Cells were collected by aspiration (marrow, peritoneal macrophages), surgical biopsy (node, tumour, thymus), or venipuncture (peripheral blood) from cats anaesthetized with ketamine. Peritoneal macrophages were collected 4 days after intraperitoneal inoculation of thioglycollate. Partial purification of mononuclear cells from marrow and blood was by density separation on Ficoll-metrizoate gradients (specific gravity 1,077). Marrow and peritoneal macrophages cultured in McCoys 5A with 20% (marrow) to 40% (macrophages) horse serum by modifications of the procedure of Dexter and Testa[34]. PBML, lymph node neoplastic lymph node, and thymus were cultured in RPMI 1640 and 20% fetal calf serum[19]. A minimum of 10^6 freshly isolated or cultured cells in 1 ml were disrupted by two freeze-thaw cycles prior to viral infectivity (VI) assay[23]; 0.2 ml of disrupted cell-associated inoculum and 0.2 ml of cell-free supernatant from each culture were each applied to 5×10^4 indicator clone 81 cells in 24 cluster dishes. VI data, expressed as FFU per 10^6 mononuclear cells, is the sum of cell-associated virus and cell-free virus for each cat positive for reactivated virus, averaged between the number of cats positive for reactivated virus from marrow versus node, etc. The ranges for the individual VI sums are indicated in brackets. ND, not determined.

from cultured marrow cells and a minor subset of nodal lymphocytes. These data suggest that self-limiting (regressive) FeLV infections are actually latent (nonproductive) infections of myelomonocytic precursor cells in the bone marrow and Protein A-reactive cells in the lymph nodes.

A similar coupling of virus latency *in vivo* with viral reactivation *in vitro* described for the putative human herpesviral oncogen, the Epstein–Barr Virus (EBV)[24,25] has been attributed to the presence versus absence of a host immune response against virally infected cells. By analogy, while those cells expressing FeLV antigens would be eliminated in regressor cats, nonproductively infected cells would survive. Therefore, we investigated the role of host antiviral defenses in the maintenance of FeLV infections in their dormant phases. Regressor cats mounted both cell-dependent and antibody-dependent killing of autochthonous marrow cells with reactivated virus (Table 2) but did not kill freshly isolated marrow cells. Cells from FeLV-naive cats had minimal cytotoxicity (<20%) against autochthonous freshly isolated or cultured marrow cells and peritoneal macrophages (data not shown). Regressor PBML (but not regressor sera) also were cytotoxic for autochthonous, non-transformed peritoneal macrophages (Table 2) negative for demonstrable FeLV production (Table 1); a finding that we do not understand, but is similar to the recognition of lymphocyte-defined membrane antigen on nonproductively infected B cells by killer cells in EBV-exposed people[26]. The biological relevance of the killing of FeLV-infected marrow cells by immune PBML and sera is suggested by the correlation of decreases in circulating neutrophil and lymphocyte numbers with curtailment of virus replication and appearance of FOCMA antibody in regressively infected cats[2,27].

The early containment in haemolymphatic tissues and establishment of regressive versus progressive infection *in vivo* is corticosteroid (CS)-sensitive[28]. *In vitro* studies have shown that minority populations of feline macrophages and lymphocytes are susceptible to productive FeLV infection[19,29] and that the permissiveness of macrophages but not lymphocytes to FeLV infection can be augmented by CS[19,29]. To examine this further we investigated the effect of CS on latent FeLV infections *in vivo* and *in vitro*. Cats with established regressive FeLV infection were treated with 10 mg per kg methylprednisolone acetate twice weekly for 4 successive weeks. They developed productive FeLV infection in marrow and diminished antibody to FOCMA-L 1–2 weeks after initiation of CS treatment (Table 3). While 3 of 5 cats were able to contain reactivated FeLV, 2 of 5 cats remained persistently viraemic 135 days after initiation of treatment. Comparable non-CS-treated untreated regressors maintained for 2–3 years in similar environments have never developed productive infection[4].

Reactivation of FeLV from latently infected marrow myelomonocytic precursor cells and from peritoneal macrophages but not from lymph node or PBML occurred *in vitro* following CS treatment (Table 4). Reactivation of FeLV was associated with induction of cytoplasmic GSA in 15–30% (mean 21%) of untreated regressor cat bone marrow cells and 20–32% (mean 25%) of CS-treated marrow cells. The CS-mediated 2–3-fold amplification of viral production, therefore, is perhaps due to increased viral replication in a fixed population (20–25%) of marrow cells that contain latent FeLV infection.

Both lymphocytes and macrophages are critical to the early restriction of reactivated FeLV infection. However, ultimately T cells of marrow origin which migrate to the thymus are transformed[2,30]. The relationships between the target cells for latent infection (myelomonocytic and T_γ cells), acute infection (B cells and myelomonocytic cells)[2,19] and transformation (T cells)[30] are as yet undetermined.

Our findings suggest that most cats infected by FeLV develop persistent viral infection of marrow cells. A minority of cats

Table 2 Cytotoxic immune responses of FeLV regressor cats with reactivated infections

	Microcytotoxicity (MCT) target					
	Marrow			Peritoneal macrophages		
		% Killing			% Killing

Media control	0/6	0		0/5	0	

500 marrow cells or peritoneal macrophages from regressor cats were seeded in triplicate in 96-well cluster dishes and cultured as described in Table 1 to permit *in vitro* FeLV reactivation. On day 6, nonadherent cells were aspirated and the adherent cells washed twice with fresh media before the addition of autochthonous cells, serum or reference serum. Serum were diluted 1:4 in media and added in 0.05-ml aliquots. For antibody-dependent cell-mediated cytotoxicity (ADCC), washed adherent cells were incubated with heat-inactivated (ΔH, 56 °C, 30 min) autochthonous serum for 30 min at 37 °C, washed twice and incubated with plastic nonadherent PBML at an effector:target (E:T) ratio of 50:1. For cytotoxic T lymphocytes (CTL), autochthonous plastic nonadherent BML only were added at an E:T ratio of 50:1. For complement-mediated lysis (CML), fresh or fresh-frozen autochthonous serum (regressor or pre-exposure serum) was added. Alternatively, ΔH reference goat anti-FeLV serum and 0.05 ml of fresh FeLV-naive cat complement[35] diluted 1:4 in media were added. To evaluate the complement-independent, cytostatic potential of regressor serum alone, ΔH regressor, reference, or pre-exposure serum was added. Cytotoxicity media was RPMI 1640–20% fetal calf serum. Plates were incubated for 20 h at 37 °C to allow lysis by cat complement[35] and nonadherent cells were removed by washing. Plates were stained with Wright Giemsa and examined for morphological evidence of target cell necrosis. % Killing is the arithmetic mean of triplicate wells for each of the no. of cats positive for MCT: (>30% killing of variable versus media control was significant at $P < 0.05$ by Student's paired *t*-test); and

$$\%\ \text{Killing} = 100 - \frac{\text{No. of viable adherent cells in variable well}}{\text{No. of viable adherent cells in media control well}}$$

Table 3 Effect of adrenal corticosteroids on latent FeLV infections *in vivo*

	No. of cats positive for GSA in:		Marrow VI			FOCMA-L	
				Titre		Antibody	
Days post treatment	Marrow	Blood	No. positive	Mean	(Range)	Mean	(Range)
0	0/5	0/5	0/5	<5		71	(32–256)
7–14	1/5	1/5	4/4	22	(15–30)	9	(<2–32)

63–135	2/5	2/5	2/5	732	(200–1175)	32	(16–64)

Five adult regressors were treated with 10 mg per kg methylprednisolone acetate (Depo-Medrol, Upjohn) at days 0, 4, 7, 11, 14, 18, 21. Mononuclear and polymorphonuclear cells in blood and marrow smears were examined for FeLV GSA by fixed cell immunofluorescence[13]. A minimum of 10^6 freshly isolated marrow cells were disrupted by two freeze-thaw cycles and assayed for VI[15]. VI is expressed as mean FFU per 10^6 cells. Antibody to FOCMA was determined by indirect membrane immunofluorescence using FL-74 target cells[5,6] and is expressed as geometric mean titre.

Cells were obtained from adult regressors and cultured as described for Table 1. 10^{-6} M CS (hydrocorticosone hemisuccinate, Solucrotef, Abbot) was included as indicated. VI is expressed as FFU per 10^6 cells (freeze-thaw lysate); % GSA-positive cells is expressed as arithmetic mean.

experience highly expressed persistent infections of marrow haemolymphatic progenitor cells, lymphoid tissues and epithelia[2], with consequent virus excretion[31], immunosuppression[32,33] and subsequent FeLV-related proliferative or antiproliferative disease[4]. Most FeLV-exposed cats (>70%), however, develop transient productive infection of haemolymphatic cells which is curtailed by host immune responses[2,5]. Nevertheless, FeLV persists as an integrated latent infection in marrow myelomonocytic precursor cells and (certain nodal) T lymphocytes and can be reactivated by liberation from host immunological controls through culture *in vitro* or immunomodulation *in vivo*. Comparable degrees of viral recrudescence *in vivo* may occur in response to endogenous hormones, senescence, or other immunosuppressive or promoting influences. These observations provide both a progression and a link between host–retrovirus relationships in the cat and those species in which greater degrees of viral genomic latency predominate, such as the ecotropic retroviral infections of cattle, gibbon apes, wild mice and the oncogenic human, simian and avian herpesvirus infections.

The use of semisolid medium for the culture and cloning of haematopoietic cells[1,2] has helped our understanding of their proliferation and differentiation. It has been shown that mixed colonies of granulocytes and macrophages developed, in the presence of colony-stimulating factor (CSF)[3,4], from their common precursor, granulocyte–macrophage colony-forming cells (GM–CFC)[5]. Attempts at recloning these colonies in semisolid medium suggested that granulocytes and macrophages were differentiated cells incapable of further proliferation[6,7]. However, our studies on cultures of larger numbers of cells[8] demonstrate that while this may be the case for granulocytes, macrophages seem to be capable of long-term proliferation.

The bone marrow for culture of GM-CFC was obtained from ICR SPF mice (Velaz). We used the technique of Metcalf[9] to establish the primary culture; MEM medium[10] was supplemented with 0.2% Bactotryptose (Difco)[11], 20% heat-inactivated pooled human serum (HS) or native fetal calf serum (FCS) (VŠV), 10% lung conditioned medium (LCM)[12], and 0.34% Bacto-Agar (Difco). For the culture we used Müller flasks (Cavalier). The primary culture was established from 5×10^5 nuclear bone marrow cells in 5 ml of medium. After 7 days at 37 °C in an ambient atmosphere plus 5% CO_2, the cells were counted and then transferred to fresh agar medium at a minimum concentration of 5×10^4 per 5 ml. Further passages were done in the same conditions approximately every 15 days. The cells in semisolid agar medium were stained with acetoorceine.

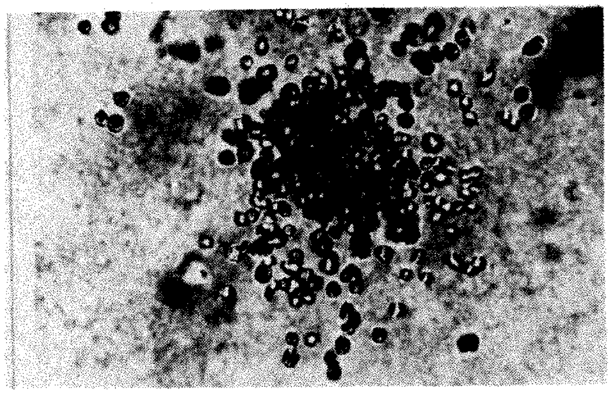

Fig. 1 A colony of macrophages from normal mouse bone marrow grown in semisolid medium; 15-day culture after the 22nd passage (330 days *in vitro*). Native preparation. ×63.

Cells of the 20th passage were transferred to liquid medium for examination and 1 ml aliquots were put into Leighton test tubes with a cover glass. After 3 weeks of culture, colonies of adhering cells suitable for processing were formed on the cover glass.

Pinocytosis was studied by means of dextran sulphate (molecular weight (MW) 5×10^5; Pharmacia); phagocytosis by means of latex particles (Imuna) and a suspension of autoclaved yeast. The receptors for IgG, complement, and IgM were determined by mouse antibodies to sheep erythrocytes. Lysozyme was demonstrated by anti-lysozymal serum using immunofluorescent techniques. The tests were performed according to Goud *et al.*[13] and the peroxidase reaction was carried out according to Graham and Karnovsky. For the determination of nonspecific esterase α-naphthyl acetate was used which could be blocked by E-600 (3×10^{-5} M). For the determination of chloroacetyl esterase, naphthol-ASD-chloroacetate and acid phosphatase naphthol-ASBI-phosphate were used. The coupler was hexazonium-*p*-rosaniline throughout. The procedures are described by Lojda *et al.*[14].

Ten macrophage cell lines have been obtained so far, the first of which is now in the 22nd passage (330 days *in vitro*) in

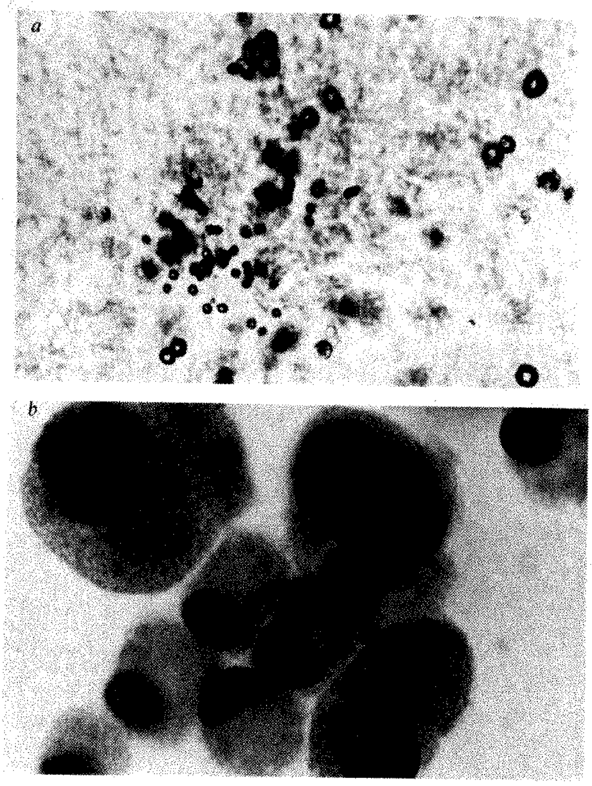

Fig. 2 *a*, A cluster of macrophages (starting colony) from a 7-day culture after the 15th passage in semisolid medium. The cluster consists of cells of various sizes. Small cells (10–14 μm in diameter) predominate in the culture. It is these cells which proliferate most readily are believed to maintain the continuous growth of the culture. Native preparation. ×30. *b*, Small and large macrophages; 15-day culture after the 15th passage in semisolid medium. Fixed and stained with acetoorceine. ×630.

medium with HS; the other three are in the 19th, 16th and 15th passage, and six lines are between the 5th and 10th passage. All of the latter nine lines were grown in FCS-containing medium. The number of seeded cells increased fivefold in ∼15 days after every passage. The macrophages grew in colonies (>40 cells) (Fig. 1), and clusters (3–40 cells), with cells varying in size from approximately 10 μm to 30 μm (Fig. 2). Larger colonies normally consist of smaller cells and large macrophages are frequently found singly or in clusters. When stained in agar medium, both large and small cells show excentrically located nuclei with relatively rich cytoplasm (Fig. 2*b*).

Pinocytosis was found in 97.2% of cells, 95.8% of cells phagocytosed latex particles, and 93.6% phagocytosed yeast (Fig. 3). Receptors for IgG and complement were present in 89.3% and 86.1%, respectively but IgM-receptors could not be demonstrated. The immunofluorescent test for lysozyme was positive.

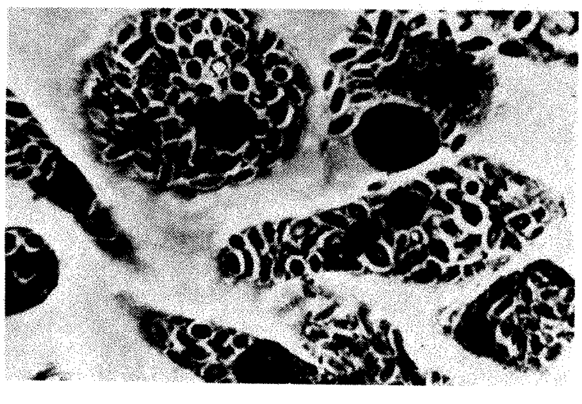

Fig. 3 Macrophage phagocytic activity after 20th passage. When transferred to liquid medium, phagocytes formed colonies of adhering cells on the surface of the cover glass. Oval forms within the cells are yeasts. Fixed with methanol. Phase contrast; ×360.

Peroxidase was negative in all cells. Nonspecific esterase was found in all cells, its activity being almost completely blocked by E600, and persisted only sporadically. Similarly, chloroacetyl esterase and acid phosphatase were positive in all cells. The activity of the hydrolases tested was high in most of the cells.

The assumption that the passaged cells are macrophages is supported by the demonstration of receptors for IgG and complement, and the absence of receptors for IgM[13], and by the cytochemical examination, despite remarkably high chloroacetyl esterase activity.

Macrophages can be preserved in liquid medium for many weeks[15,16], but are believed to be incapable of passaging[16]. However, the use of semisolid media, which minimizes the number of cells adhering to the culture surface, allows long-term growth of macrophage populations from the original mixed granulocyte–macrophage colonies. The medium for long-term culture and passaging of macrophages must be supplemented with a suitable serum and LCM. The establishment of long-term cultures and passaging of macrophages from normal mouse bone marrow *in vitro* will be a useful tool for the further characterization of these very important cells.

Biosynthesis of membrane factor B by mouse peritoneal macrophages

Yuet M Ooi & Boon S. Ooi

Division of Nephrology, Department of Internal Medicine,
University of Cincinnati Medical Center, Cincinnati,
Ohio 45267, USA

The biosynthesis of many of the complement proteins by cells of the monocyte-macrophage series has been established[1]. Studies on these cells using radiolabelled amino acids have demonstrated synthesis of precursor proteins (pro-complement)[2–5], and the native complement protein similar in size to that found in the plasma. However, synthesis of membrane complement proteins has not been demonstrated, although it has been suggested by previous studies using indirect techniques[6–10]. In particular, there is evidence for the membrane-associated factor B in human lymphocytes[11,12]. We report here that resident and thioglycollate-stimulated mouse peritoneal macrophages synthesized, in short-term primary cultures membrane factor B of molecular weight (MW) 95,000 and secreted factor B (MW 90,000) as single chain polypeptides. We also found a large single chain polypeptide with an approximate molecular weight of 195,000, which may be the putative factor B precursor.

Resident and thioglycollate-stimulated mouse (C57BL/6J) peritoneal macrophages were cultured at 37 °C for 18–48 h in Dulbecco's modified Eagle's medium (DMEM) in serum-free conditions in the presence of 60 mM 6-ε-amino caproic acid and radiolabelled with 35 S-methionine (150 μCi ml^{-1} of medium). At the end of the culture, the supernatants of the

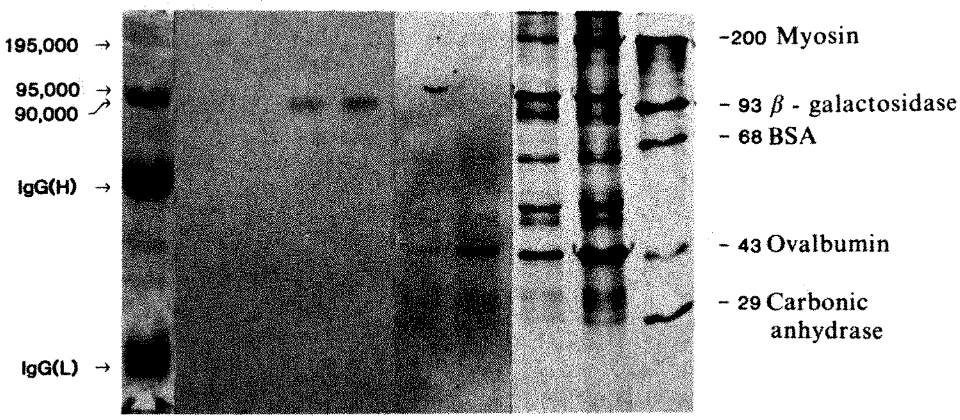

Fig. 1 SDS (1%)-polyacrylamide (9%) gel electrophoresis (Laemmli)[23] of reduced and alkylated ^{35}S-methionine labelled intracellular factor B antigen from resident and thioglycollate-stimulated mouse peritoneal macrophages (mouse strain C57BL/6J). Resident and thioglycollate-stimulated cells were collected and cultured as described previously[5]. Resident cells were plated at 13×10^6 and thioglycollate-stimulated cells at 10×10^6 cells on to 60×15 mm dishes in Dulbecco's modified Eagle's medium, 20% FCS (heated at 56 °C for 2 h). The cells were incubated in a humidified atmosphere of 95% air : 5% CO_2 at 37 °C for 45 min to allow adherence and then non-adherent cells were rinsed off by several washes with Hank's balanced salt solution (HBSS). The adherent cells were cultured for 18 h in DMEM lacking cold methionine (incomplete DMEM) and containing 60 mM 6-ε-amino caproic acid (EACA) and ^{35}S-methionine (150 μCi ml^{-1}) specific activity >50 Ci mmol^{-1}; NEN). At the end of the culture, the medium was collected and the adherent cells were lysed with cold lysate buffer consisting of Tris-HCl (50 mM), KCl (100 mM), Triton X-100 (0.5%), deoxycholate (0.5%), EDTA (10 mM), EACA (100 mM), and phenylmethylsulphonyl fluoride (PMSF; 2 mM). Radiolabelled culture material was centrifuged at 10,000 r.p.m. in a microfuge at 4 °C for 45 min. To the extracellular culture medium was added EDTA (10 mM), PMSF (2 mM), and EACA (100 mM) final concentration and the extracellular culture medium was centrifuged at 150*g* for 10 min. The radiolabelled supernatants were immunoprecipitated with cross-reactive goat IgG antibody to human factor B (Atlantic Antibodies), added at two-fold antibody excess to yield 30 μg of immunoprecipitate, in the presence of ovalbumin with normal mouse serum as cold carrier[5]. The control was mouse antiserum to ovalbumin reacted with ovalbumin in the presence of goat IgG; the antibody to ovalbumin was absorbed with mouse serum before use. After incubation for 3 h at room temperature, the immunoprecipitates were washed extensively. The precipitates were solubilized by boiling for 4 min in 80 μl of sample buffer *p*H 8.1 consisting of: SDS (1%), Tris-HCl (10 mM), Na_2-EDTA (1 mM) and β-mercaptoethanol (4%). After boiling, the sample was incubated with 120 mM iodacetamide for 1 h at 37 °C and centrifuged at 10,000 r.p.m. for 2 min. The fluorograph following SDS-PAGE was developed by standard techniques[24] after fixing the slab gel in 7% glacial acetic acid with 50% methanol, followed by 1 h in Enhance (NEN) and 1 h in distilled water. The gel was dried under vacuum and exposed to a Kodak X-Omat-RP film at −70 °C for 7–10 days, depending on the radioactivity of the immunoprecipitates. Lane *a* shows mouse factor B antigen precipitated from cold carrier mouse serum stained with Coomassie blue, migrating as a protein of MW 90,000. The goat antibody is also detected: H, heavy chain; L, light chain. Lanes *b* to *i* represent the fluorograph of the SDS-PAGE of immunoprecipitated ^{35}S-methionine-labelled protein. Lane *h* shows newly synthesized ^{35}S-methionine-labelled reduced and alkylated intracellular factor B antigen from lysates of cultures of resident mouse peritoneal macrophages. Note the presence of the 195,000-MW and 95,000-MW bands compared with the control immunoprecipitate (*f*). Lane *i* shows these bands but is from intracellular factor B antigen from thioglycollate-stimulated mouse macrophages, which is not found in the control immunoprecipitate from stimulated cells (*g*). In *d* (resident cells) and *e* (thioglycollate-stimulated cells), reduced and alkylated extracellular factor B antigen is shown as a protein band of 90,000 MW, not detected in the controls (*b*, resident cells; *c*, thioglycollate-stimulated cells). ^{14}C-labelled molecular weight markers are shown in *j*.

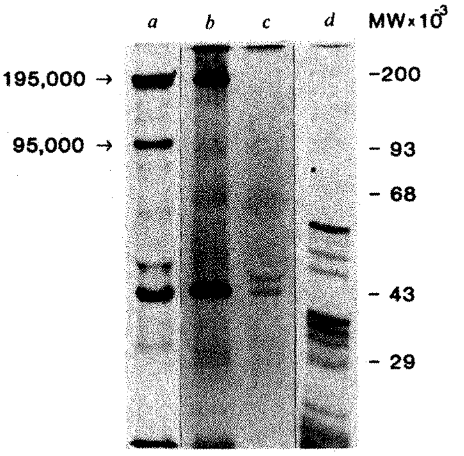

Fig. 2 For these experiments thioglycollate-stimulated and control cells cultured for 18 h in serum-free DMEM containing 60 mM ε-aminocaproic acid (EACA) and 150 μCi ml^{-1} ^{35}S-methionine. The cells were rinsed and incubated with trypsin (tosylphenylethylchloromethylketone, TPCK) added at 10 μg ml^{-1} of HBBS at 37 °C for 45 min. At the end of the incubation, the cells were rinsed and lysed with cold lysate buffer with added protease inhibitors (EDTA, EACA and PMSF). A similar lysate was prepared without protease inhibitors and then incubated at 37 °C for 45 min with 10 μg ml^{-1} of trypsin. At the end of the incubation a twofold excess of soybean trypsin inhibitior (SBTI) was added. Immunoprecipitation and SDS-PAGE was then performed. Lane *b* shows the factor B precipitate of the ^{35}S-labelled thioglycollate-stimulated macrophages trypsinized off the cell surface. Note the disappearance of the 95,000-MW protein band and the presence of the 195,000-MW polypeptide chain. In lane *a* is the non-trypsinized control. Lane *c* is the control immunoprecipitation with anti-ovalbumin of a culture following trypsinization showing absence of the corresponding bands. Lane *d* shows precipitate of the lysate not treated with protease inhibitors. Note the disappearance of the 195,000-MW and the 95,000-MW polypeptides and the generation of several small peptide fragments. ^{14}C-labelled molecular weight standards are shown on the right.

radiolabelled medium and of the cell lysates were immunoprecipitated with goat IgG antibody to human factor B, which is cross-reactive with mouse serum factor B. The antibody was shown by immunoelectrophoresis to be specific for factor B antigen of human and murine serum. Factor B antigen immunoprecipitated from mouse serum with the same antibody migrated as a single chain polypeptide of 90,000 MW (Fig. 1*a*) on SDS (1%) polyacrylamide gel (9%) electrophoresis (SDS-PAGE) of the immunoprecipitate. A similar SDS-PAGE of the immunoprecipitate obtained from ^{35}S-methionine labelled cell lysates of resident and thioglycollate-stimulated cells, detected several intracellular polypeptide chains and intermediate fragments: a large 195,000-MW polypeptide chain, a 95,000-MW chain, and several smaller MW polypeptide chains (88,000–64,000 and smaller) (Fig. 1*h* and *i*). The SDS-PAGE of the immunoprecipitate obtained from the extracellular culture yielded a single chain polypeptide of 90,000 MW (Fig. 1*d* and *e*) similar in size to that of mouse serum factor B.

^{35}S-methionine labelled thioglycollate-stimulated cells were incubated with trypsin (10 μg ml^{-1}) at 37 °C for 45 min, to remove membrane proteins, then rinsed and lysed. SDS-PAGE of the factor B immunoprecipitates of these cell lysates did not show the band representing the 95,000 MW polypeptide chain, suggesting its association with the membrane (Fig. 2*b*); control cells not incubated with trypsin retained their bands (Fig. 2*a*).

The intracellular 195,000-MW polypeptide was unaffected by trypsinization of the cell surface. Evidence for its intracellular location was obtained by experiments in which intracellular lysates were trypsinized; in these conditions the 195,000-MW protein and the 95,000-MW polypeptide were digested (Fig 2*d*). To establish whether the 95,000-MW polypeptide chain was a membrane component, macrophage plasma membrane proteins were labelled by lactoperoxidase-catalysed radioiodination. The immunoprecipitate showed the presence of the 95,000-MW polypeptide (Fig. 3*b*) identical in size to the newly synthesized 95,000-MW polypeptide chain obtained from ^{35}S-methionine labelled cells (Fig. 3*a*). Macrophages cultured in the presence of cycloheximide showed almost total abrogation of the expression of the 95,000-MW polypeptide chain (Fig. 3*c*) followed by its reappearance in cells radioiodinated after a 36 h culture in fresh medium following the removal of cycloheximide (Fig. 3*e*); these experiments therefore established *de novo* synthesis of this molecule and ruled out the possibility of absorption onto the cell membrane.

To further exclude absorption of membrane factor B studies were done using radiolabelled non-adherent peritoneal cells which did not show the presence of the 95,000-MW polypeptide chain (Fig. 3*f*). As a fourfold excess of radiolabelled non-adherent cells compared to the radioiodinated adherent cell population was examined, differential absorption of protein could not account for the different absorption patterns. Finally, it must be noted that on parallel SDS-PAGE analysis of intracellular, extracellular, and membrane labelled material, the extracellular (secreted) factor B has a different molecular size (MW 90,000) compared to the membrane and the cell lysate factor B (MW 95,000), which indicates that there are two distinct molecules one of which is a membrane component.

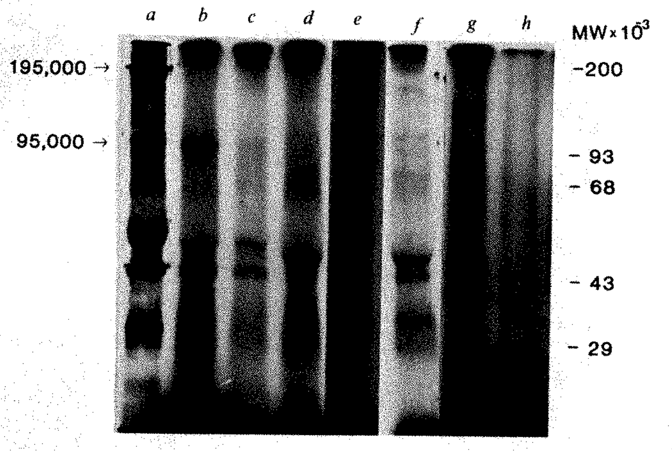

Fig. 3 SDS-PAGE of reduced and alkylated factor B antigen from ^{125}I-labelled mouse peritoneal macrophages radioiodinated for plasma membrane proteins radioiodinated by the Na^{125}I–lactoperoxidase-catalysed reaction[10] with slight modifications. For these experiments, resident and thioglycollate-stimulated peritoneal cells were cultured in serum-free complete DMEM, 60 mM EACA. After culture the cells were released by incubation at room temperature for 1 h with lidocaine (20 mM) in complete DMEM, 20% heated FCS, washed with PBS and then suspended at 1×10^7 cells ml^{-1} for lactoperoxidase radioiodination. The heated FCS contained no detectable factor B antigen. For the cycloheximide experiments, thioglycollate-stimulated cells were cultured for 4 h with cycloheximide added to a concentration of 7·5 μg ml^{-1} of complete DMEM. Cycloheximide was removed after 4 h, the cells were rinsed and the culture continued for 36 h in fresh medium containing 60 mM EACA; a control culture contained no cycloheximide. At the end of the culture, the adherent cells were released with lidocaine and radioiodinated for analysis of plasma membrane proteins. The cell suspension was reacted with 250 μCi of carrier-free Na ^{125}I, an equal volume of NaI (1 mM solution), lactoperoxidase (40 U; Sigma), glucose oxidase (1 U; Sigma), and the mixture was shaken intermittently at 4 °C for 25 min. After incubation, the cells were washed with PBS containing (mM): glucose 20, EDTA 10, PMSF 2, EACA 100 and NaI 75; and finally with complete DMEM, 20% heated FCS containing EDTA, PMSF, EACA and NaI as above. The cells were lysed with cold lysate buffer then centrifuged at 10,000 r.p.m. for 35 min; the supernatants were immunoprecipitated for factor B antigen. Parallel control precipitation was with control antiserum to ovalbumin. The immunoprecipitate was reduced and alkylated and subjected to SDS-PAGE; the autoradiograph is shown. Lane *a* shows ^{35}S-methionine-labelled factor B antigen from a 48 h culture of thioglycollate-stimulated mouse peritoneal macrophages for comparison with radioiodinated membrane factor B antigen. Note the smaller MW protein bands. Lanes *b–e* and *g, h* show lysates of peritoneal macrophages and *f* shows lysates from non-adherent peritoneal cells. Note (1) the presence of the 95,000-MW protein band in *b*, representing factor B antigen; (2) the almost total abrogation of the 95,000-MW band in cycloheximide-treated ^{125}I-labelled thioglycollate-stimulated macrophages (*c*); (3) the absence of the corresponding band from the control precipitate (*d*); (4) the presence of the corresponding 95,000-MW protein band in the stimulated cells after 36 h of culture in fresh medium following a 4 h exposure to cycloheximide (*e*); (5) the absence of this band from non-adherent stimulated cells from 48 h cultures (*f*); (6) the presence of 95,000-MW protein band in radioiodinated resident cells (*g*); and (7) the absence of the corresponding band in the control precipitate from macrophages (*h*). ^{14}C-labelled molecular weight markers are shown on the right.

These findings establish the 95,000-MW polypeptide chain detected in cell lysates of mouse macrophages as membrane factor B of molecular weight 95,000, synthesized in short-term primary culture. Secreted factor B of molecular weight 90,000 was also demonstrated. A larger 195,000-MW polypeptide, pro-factor B, has been identified. In studies[13] using pulse-chase and conversion experiments, the 195,000-MW molecule was shown to be precursor, giving rise to membrane and native factor B. Smaller fragments were also demonstrable and probably result from degradation by proteolytic digestion, as was evident in previous studies[4]. This was probably not due to the specificity of the antibody which was described earlier and is further supported by the presence of only a single band on analysis of immunoprecipitated extracellular material as well as of mouse serum. Another explanation, though less likely, is the presence of incompletely synthesized chains. The biosynthesis of native factor B by mouse macrophages and by human monocytes and the function of plasma factor B have been established previously[14–22]. The functionl activities of the three proteins reported here have yet to be determined. It may be that the macrophage assembles such complement proteins as a defence mechanism, either as a recognition or as an effector unit.

We thank Mrs V Henry for her help. This work was presented at the 9th International Complement Workshop in November 1981 and is supported in part by a grant AI 16729 from the N.I.A.I.D., NIH.

A bifunctional gene product involved in two phases of the yeast cell cycle

J. R. Piggott, R. Rai & B. L. A. Carter

Department of Genetics, University of Dublin, Trinity College,
Dublin 2, Ireland

The cell cycle in *Saccharomyces cerevisiae* is divided into two distinct phases. Unbudded, mononucleate cells in the G1 phase can react to relevant environmental changes by mating[1], sporulating[2], or by entering stationary phase[3]. DNA synthesis and bud initiation occur almost simultaneously and mark 'commitment' to the completion of mitosis. Temperature-sensitive mutations at the *cdc28* locus are known to cause arrest in the G1 phase of the cell cycle at the restrictive temperature[4,5]. Here we show that the *cdc28* gene product is also active in post-G1 cell cycle functions, and that a different property of the gene product may be required for each phase of the cycle in which it acts.

The *S. cerevisiae* strain RJB-1 was obtained during a search for nonsense mutations in the strain FM11 (ref. 6). At 37 °C, RJB-1 arrested with the budded, mononucleate morphology

0028–0836/82/290391—03$01.00

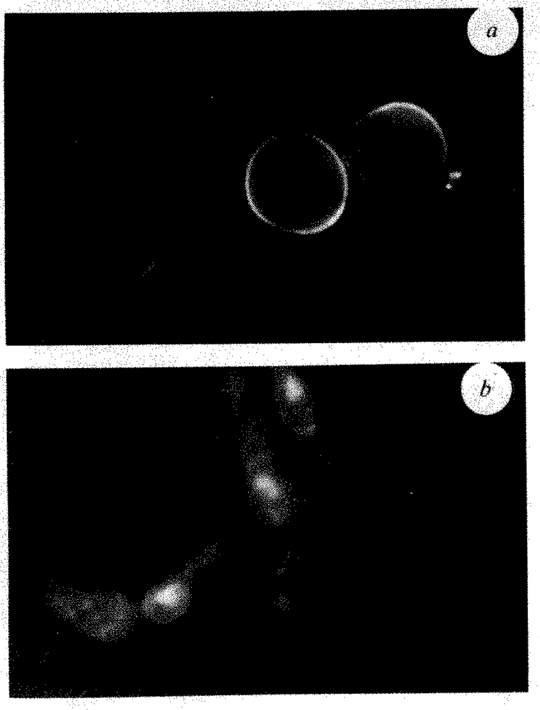

Fig. 1 *a*, The unbudded morphology characteristic of G_1 arrest seen in *cdc28-6* cells after 3.5 h at 37 °C, stained with calcofluor and photographed under UV light. *b*, The mononucleate, budded morphology of RJB-1 (*cdc28-1N*) cells after 3.5 h at 37 °C. The nuclei are stained with diamidinophenyl indole[18] and the cell outlines revealed by calcofluor under UV light.

illustrated in Fig. 1. When crossed with a wild-type strain, RJB-1 yielded a temperature-insensitive diploid, and 42 tetrads from this diploid showed four-spore survival and 2 : 2 segregation for temperature sensitivity. The homogeneity of its arrest phenotype suggested that RJB-1 carried a cell cycle mutation[7], and it was shown to complement the *cdc* mutants 1 to 40, except for *cdc28-1* and *cdc28-6*. Dissection of 32 tetrads from the RJB-1 × *cdc28-1* cross, and 59 tetrads from the RJB-1 × *cdc28-6* cross, yielded no wild-type spores. We therefore concluded that RJB-1 carried a new mutation at the *cdc28* locus. As the phenotype of the new mutant suggested a lesion in nuclear division, we provisionally named the new *cdc28* allele, *cdc28-1N*.

When yeast cells of *a* mating type are treated with *α*-factor, a hormone-like small polypeptide produced by cells of *α* mating type, they undergo reversible G_1 arrest[1]. The cells are sensitive to *α*-factor until ~15 min before the appearance of a visible bud[8]. Figure 2 shows the pattern of DNA synthesis in cells carrying the *cdc28-6* and *cdc28-1N* mutations at 37 °C after release from *α*-factor-induced arrest at 24 °C. The *cdc28-6* cells showed no significant DNA synthesis, remaining unbudded, while the *cdc28-1N* cells exhibited appreciable DNA synthesis. Microscopic examination revealed 100% bud initiation in the *cdc28-1N* culture, although there was no increase in cell number. In the reciprocal shift, that is, arrest at 37 °C followed by transfer to 24 °C in the presence of *α*-factor, *cdc28-6* cells remained arrested in G_1, as described by Hereford and Hartwell[9], while *cdc28-1N* cells divided once at 24 °C before undergoing *α*-factor arrest. Thus, the *cdc28-1N* mutation acts at a point in the cell cycle which is unambiguously later than the *α*-factor or 'start' step, while the *cdc28-1* and *cdc28-6* execution points cannot be separated from 'start' by the reciprocal shift technique[9].

Table 1 The behaviour of recently budded *cdc28-6* cells at 37 °C

Time after shift to 37 °C (min)	Unbudded, 1 nucleus (%)	Budded, 1 nucleus in mother (%)	Budded, 1 nucleus in bud (%)	Budded, nucleus dividing (%)	Budded, binucleate (%)
0	48	48	–	–	4
70	33	48	2	4	13
110	34	49	5	–	12
130	32	49	5	–	14

An exponentially growing culture of *cdc28-6* in YEPD (1.5×10^6 cells ml^{-1} in 2% glucose, 2% Bacto-peptone and 1% yeast extract solution) was arrested in G_1 by exposure to *α*-factor (10 U ml^{-1}) at 24 °C for 3h. The *α*-factor was removed by Millipore filtration of the cells, which were then washed with two volumes of fresh medium. The cells were resuspended in fresh YEPD and allowed to recover at 24 °C until 50% had initiated a bud, when a 25-ml sample was shifted to 37 °C. The control cells divided at 24 °C, 100 minutes after T_0 (zero time). Samples taken at the time indicated were stained with diamidinophenyl indole[18] to reveal nuclear morphology. The increase in per cent binucleate cells was due to cells which had already passed both cell cycle blocks at the time of the shift. At least 150 cells were scored for each sample.

The *cdc28-6* × *cdc28-1N* and *cdc28-1* × *cdc28-1N* diploids arrested at 37 °C with the budded morphology typical of *cdc28-1N*. As *cdc28-1N* is recessive, this suggested the presence of a nuclear division defect in the G_1 arrest alleles. To test this possibility, *α*-factor-arrested *cdc28-6* cells were allowed to recover from G_1 arrest at 24 °C, and at 20-min intervals, samples from the recovering culture were shifted to 37 °C. It was found that the cells were unable to divide at 37 °C until 35 min after bud initiation (that is, 'start'). The *cdc28-1N* mutant shows similar behaviour (data not shown). The results presented in Table 1 confirm that *cdc28-6* cells which have recently budded, and therefore passed the 'start' event, cannot complete cell division at the restrictive temperature. Thus *cdc28-6* harbours a lesion in the nuclear division process which has been masked previously by its temporal proximity to the 'start' lesion also present in this strain.

Evidently, mutation at the *cdc28* locus may confer a defect in nuclear division alone, or in both 'start' and nuclear division functions. So far, *cdc28-1N* is the only allele at this locus known to affect nuclear division exclusively. In contrast, a range of *cdc28* G_1 arrest mutants is already available. Whether or not all such mutants show the double cell cycle lesion reported here for *cdc28-6* is unknown. If 'start only' mutants of *cdc28* do exist, we might expect them to complement *cdc28-1N*, and test crosses with this allele should provide a useful preliminary screening procedure. An investigation of the mitotic behaviour of other G_1 arrest mutants (for example, *cdc37*)[5] is also required in view of these results.

The earliest cell cycle event known to be blocked by the *cdc28* mutation is spindle pole body duplication, which nor-

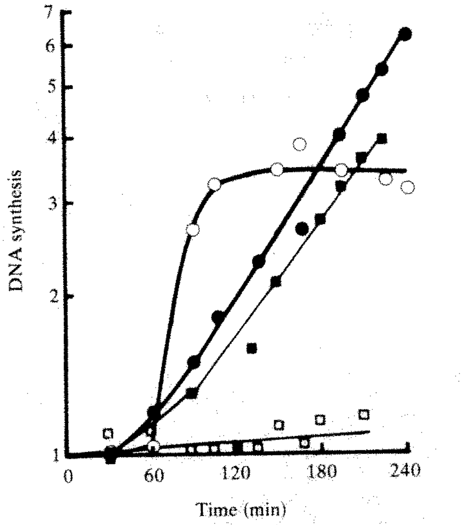

Fig. 2 DNA synthesis patterns following a shift from the *α*-factor block to 37 °C in RJB-1 (*cdc28-1N*) and ST10 (*cdc28-6*) cells. A log-phase culture (2×10^6 cells ml^{-1}) was arrested in G_1 by exposure for 3 h to *α*-factor (final concentration 10 U ml^{-1}). The *α*-factor was removed by Millipore filtration and washing with 100 ml of fresh nutrient medium. Cells were resuspended in fresh medium containing 1 μCi [2-C^{14}]uracil ml^{-1} and incubated at 24 °C or 37 °C. Samples were removed at intervals and the radioactivity incorporated into DNA was determined[19]. Results are expressed as c.p.m. relative to initial values in each experiment. ●, RJB-1 at 24 °C; ○, RJB-1 at 37 °C; ■, ST10 at 24 °C; □, ST10 at 37 °C.

mally precedes both initiation of DNA synthesis and budding[10]. As recently budded cells have already duplicated their spindle pole bodies, our results indicate that *cdc28* cannot be concerned exclusively with such duplication. Failure to complete this process does not suppress other 'start' activities in the cell cycle mutant *cdc31* (ref. 11), thus it is possible that such failure is a symptom of G_1 arrest, but not its primary cause. As bud formation can occur in the absence of DNA synthesis in *cdc7* (ref. 12), and DNA synthesis can occur in the absence of bud formation[13], it is likely that all three markers of the start event are normally subject to coordinate control by a process or structure which involves the *cdc28* gene product.

When recovering from α-factor arrest at 24 °C, *cdc28-6* and *cdc28-1N* cells showed nuclear migration into the bud before nuclear division, and this migration was inhibited at 37 °C (Table 1). As mid- and late-nuclear division require extensive nuclear mobility, and these events are apparently unaffected by *cdc28* mutations, it is unlikely that the early nuclear paralysis seen in both *cdc28-6* and *cdc28-1N* is due to a defect in microtubule formation. Nuclear division, however, requires that nuclear movements be spatially coordinated within the mother/bud junction of the dividing cell. Such coordination requires the presence of nuclear/cytoplasmic connections, and the mitotic spindle in yeast is known to connect with the cytoplasm via mictrotubules[14]. Inability to form such nuclear/cytoplasmic connections at 37 °C could well account for our results, and for the reported association of a *kar* phenotype (failure of nuclear fusion at zygote formation) with some *cdc28* mutants[15].

Nuclear division is prevented by the *cdc28-1N* mutation at the restrictive temperature, but start functions seem unaffected. This suggests that a different property of *cdc28* is required for each process in which it participates. The bifunctional nature of the *cdc28* protein may reflect functional segregation of the *cdc28* gene similar to that found at the *his4c* locus, where a single polypeptide has three enzymatic functions which can be independently eliminated by mutation[16]. On the other hand, the particular lesion present in *cdc28-1N* may be critical for nuclear division, but not start processes, at the restrictive temperature because of a different molecular environment for the gene product at both cell cycle stages. Extensive genetic and physical analysis will be required to elucidate this.

Whatever the physical basis of the bifunctionality of *cdc28*, it is interesting that the *cdc2* gene in *Schizosaccharomyces pombe* has a regulatory effect at start[17] and acts at two points in the cell cycle equivalent to those described here for *cdc28* in *S. cerevisiae*. Although no mutation has so far been reported in *S. pombe* which blocks one function in the cell cycle exclusively, it is possible that the *cdc28* gene of *S. cerevisiae* and the *cdc2* gene of *S. pombe* have equivalent roles, and that in both organisms a functional component of the nuclear division process has a role in regulation commitment to cell division.

Ligation of oligonucleotides by pyrimidine dimers—a missing 'link' in the origin of life?

Roger J. Lewis & Philip C. Hanawalt

Department of Biological Sciences, Stanford University, Stanford, California 94305-2493, USA

One of the principal photochemical reactions of DNA on exposure to UV is the formation of intrastrand cyclobutane-type pyrimidine dimers[1,2]. The efficiency of this reaction depends on both the wavelength of the UV[2] and the specific nucleotide sequence in the DNA[3]. The formation of the pyrimidine dimer and its repair in living cells have been studied extensively[4]. We have examined the possibility that pyrimidines at the ends of DNA strands may be adequately juxtaposed for dimer formation by the presence of a complementary strand, even when no phosphodiester linkage joins their sugars. In these conditions the formation of a dimer will 'ligate' two DNA strands end-to-end. We report here that thymidine oligonucleotides annealed to polydeoxyadenylate can be ligated end-to-end by UV irradiation, via thymine dimerization of the terminal nucleotides in adjacent oligonucleotides. The linkages are susceptible to direct photoreversal by 254 nm UV, as expected for cyclobutane-type thymine dimers, but they are not cleaved by the bacteriophage T4 endonuclease V, a dimer-specific DNA repair enzyme. We demonstrate that the ligating dimers are also resistant to photolyase from *Escherichia coli*. Although the phosphodiester backbone is not required for dimer formation, it is required for recognition of dimers by these DNA repair enzymes. We discuss the possibility that high molecular weight polynucleotides in primordial seas might have been generated from oligonucleotides by pyrimidine dimerization under the intense solar UV flux unattenuated by an ozone layer.

Within a continuous DNA strand, pyrimidine dimer formation proceeds as follows. An absorbed photon excites a pyrimidine base from its singlet bonding ground state to a singlet antibonding excited state. The new electronic configuration of the base reduces its van der Waals' radius, allowing an adjacent pyrimidine to move closer than the usual 3.4 Å spacing and to share the excitation energy[5–7]. This 'excimer' state can then undergo inter-system crossing into the more stable triplet state from which a pyrimidine–pyrimidine cyclobutane dimer may arise.

Our model system consisted of oligodeoxythymidylate 10 residues long $[d(pT)_{10}]$ mixed with an equal weight of polydeoxyadenylate [poly(dA)] in solution. The resulting duplex[8] melts near 25°C (ref. 9). After labelling a small fraction of the 5′ ends with ^{32}P we irradiated the DNA with UV of wavelengths >290 nm, which we hereafter call long-wavelength UV. Electrophoretic analysis on denaturing polyacrylamide gels revealed the production of high molecular weight oligomers corresponding to integral multiples of the $d(pT)_{10}$ (Fig. 1). The presence of dimers, trimers and tetramers was apparent after 30 min of irradiation. This 'ligation' of oligonucleotides was caused presumably by the formation of dimers between the first and last thymines of oligonucleotides adjacent on the complementary poly(dA). Similar irradiation of single-strand $d(pT)_{10}$ produced no effect detectable by gel electrophoresis (data not shown). We concluded that hybridization to the poly(dA) is required to maintain the oligonucleotides in a photoligatable configuration.

To quantify the amount of material in each electrophoresis band, we excised the bands from the dried gel and assayed them for ^{32}P. This allowed us to measure the kinetics of the photoligation process (Fig. 2). To compare the photoligation process with the formation of thymine dimers at internal positions, we irradiated poly(dT)·poly(dA) in identical conditions and quantified the resulting thymine dimers by TLC[10]. During the initial phase (0–30 min) of irradiation, the production of

0028-0836/82/290393—04$01.00

dimers, trimers and tetramers of the oligomers occurred, with the expected loss of material from a 10-base band in the gels. The initial rate for internal dimer production in poly(dT) · poly(dA) was similar to or slightly less than the initial rate for the production of ligating thymine dimers in our substrate (Fig. 2).

During the next phase of the process (30–60 min of irradiation) the yield of material in each band reached a plateau. In contrast, the content of internal dimers in poly(dT) · poly(dA) continued to rise rapidly during this period. On continued irradiation (60–240 min) we observed no significant change in the relative quantity of material in the respective bands.

Why does formation of ligating dimers cease while internal dimer formation continues? One possible explanation involves denaturation of oligonucleotides by internal dimers. After 30 min irradiation each oligonucleotide contained an average of one internal dimer, assuming that the rate of internal dimer formation in $d(pT)_{10}$ is similar to that in poly(dT). A dimer in oligo $d(pT)_{10}$ · poly(dA) reduces the melting temperature below that of $d(pT)_6$ · poly(dA)[11]. As the melting temperature of $d(pT)_6$ · poly(dA) is less than 9 °C (ref. 9), it seems likely that after 45–60 min of irradiation at 5–10°C very little of the $d(pT)_{10}$ was still annealed to the poly(dA), thus eliminating the end-to-end juxtaposition required for the formation of ligating dimers. Another possible explanation is that the competing production of internal dimers between the first and second or ninth and tenth thymines within the oligonucleotides prevented the production of ligating dimers between the first and tenth thymines of adjacent oligonucleotides.

One distinctive characteristic of cyclobutane dimers is their reversibility by irradiation with UV of wavelengths shorter than ~260 nm (ref. 2). To confirm that the ligating dimers were reversible by UV, we exposed $d(pT)_{10}$ · poly(dA) to long-wavelength UV to produce 'ligated' oligonucleotides, then re-irradiated the DNA with UV of shorter wavelengths (mainly 254 nm). With doses of short-wavelength UV up to 1.6×10^4 J m^{-2}, the amount of material in the ligated oligomer bands clearly decreased (Fig. 3). Quantification of the material in the bands confirmed this (not shown). This observation demonstrates photoreversibility of the ligating dimers and, as discussed below, lends support to the hypothesis that dimer-induced denaturation limits formation of ligating dimers.

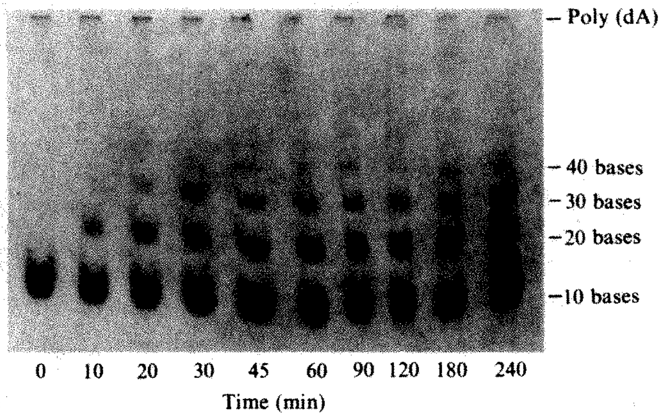

Fig. 1 Ligation of oligonucleotides by increasing irradiation with long-wavelength UV. This autoradiograph of a denaturing polyacrylamide gel shows the production of dimers (20 bases), trimers (30 bases), and tetramers (40 bases) of oligonucleotides (10 bases) by increasing irradiation with long-wavelength UV. Double-strand polymers of oligo ($d(pT)_{10}$) · poly(dA) (7850; P. L. Biochemicals) were dissolved in 0.5 ml phosphate buffer (50 mM sodium phosphate, 50 mM NaCl, *p*H 7.0) to an A_{260} of 6.0; 1 μg of this DNA was ^{32}P-labelled at the 5′ termini[20]. Mixing the unlabelled and labelled DNA yielded an activity of 10^3 c.p.m. μl^{-1} although less than 1% of the molecules were labelled. For irradiation, a fraction of the DNA solution was placed in a 1 cm glass cuvette, surrounded by water at 0 °C. The solution was stirred and nitrogen was bubbled through it before and during the irradiation. Light was provided by a focused 75 W low-pressure xenon lamp having an output of 2 J m^{-2} in the 250–260 nm band. The glass cuvette was opaque to wavelengths shorter than 290 nm and in these conditions a high equilibrium dimer yield was obtained[2]. At the times shown, 30-μl samples were removed, denatured with formaldehyde[21], and loaded onto the gel with 6 μl of 40% (w/v) sucrose. The 12.5% polyacrylamide gels were prepared and run in Peacock's buffer[22] to which formaldehyde had been added to a concentration of 2% (w/w). The buffer was recirculated during both the pre-run (> 8 h, 100 V) and the run (60 min, 250 V). The gel was dried and autoradiographed.

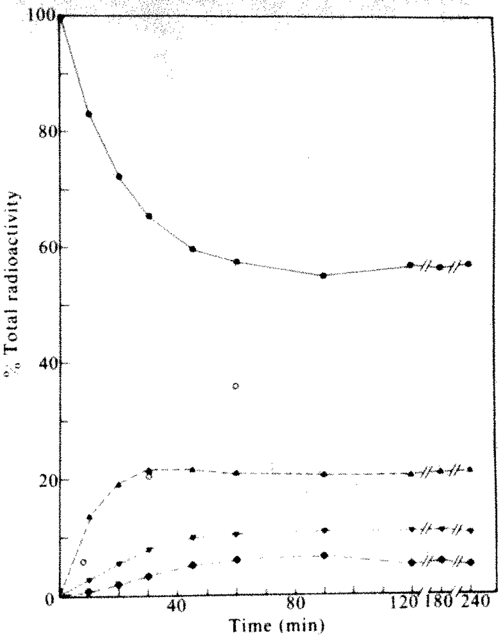

Fig. 2 Kinetics of photoligation. The radioactivity in each band (●, 10 bases; ▲, 20 bases; ▼, 30; ◆, 40) is expressed as a percentage of the total radioactivity entering each gel lane shown in Fig. 1. After the gel was autoradiographed, each band was excised and assayed for radioactivity by scintillation spectrometry in omnifluor/toluene (NEN). A separate experiment was set up to determine the kinetics of internal dimer formation in our irradiation conditions: a small amount of [2-^{14}C]poly(dT) · poly(dA) (10472; P. L. Biochemicals); was included in the cuvette during an identical irradiation of $d(pT)_{10}$ · poly(dA) and the fraction of thymines contained in dimers was measured by TLC[10]. The percentage of total ^{14}C contained in the dimer peak is shown (0). The initial rate of production for any of the products measured was determined by measuring the slope of the line joining the first two points (for example, 0 min and 10 min).

Short-wavelength UV (254 nm) can dimerize up to 39% of the thymines in poly(dT)[2], but only 20% of the thymines were dimerized after our initial long-wavelength UV irradiation of $d(pT)_{10}$ · poly(dA). Thus, the subsequent short-wavelength irradiation while apparently breaking the ligating dimers, should have actually increased the frequency of internal dimers within the oligomers. This dichotomy is understandable if one considers two effects of short-wavelength UV on a photoligated oligonucleotide. First, the internal dimers are both broken and formed, eventually resulting in a higher equilibrium frequency than originally present. This leads to denaturation of the oligonucleotide. Second, the ligating dimer is broken, but cannot be re-formed because the oligonucleotide is no longer hybridized to the poly(dA). Thus there is a loss of ligated oligonucleotides. Dimer-induced denaturation removes the oligonucleotides from a ligatable configuration after either extensive long-wavelength irradiation or after a shorter period of long-wavelength irradiation followed by short-wavelength irradiation. In the former case this simply stops the photoligation process, while in the latter case it allows us to observe photoreversibility of the ligating dimers.

It was of interest to determine whether enzymes specific for pyrimidine dimers in DNA would also recognize the ligating dimers, as this would elucidate both the nature of the ligating dimers and the mechanisms of action of these enzymes.

Photolyase from *E. coli* binds tightly to pyrimidine dimers and, on irradiation with visible light, catalyses the splitting of the dimers into the two original pyrimidines[12,13]. The splitting of a ligating dimer would result in the separation of the oligonucleotides as no phosphodiester bond connects them.

To determine whether the ligating dimers were sensitive to photolyase, we treated photoligated $d(pT)_{10} \cdot poly(dA)$ with the enzyme. We included in the reaction mixture a small amount of ^{14}C-labelled *E. coli*. DNA, the natural substrate, to confirm that the enzyme was active. After electrophoretic analysis we looked for a reduction in the amount of material in the 20-base band which would indicate splitting of the ligating dimers. We monitored splitting of pyrimidine dimers in *E. coli* DNA by TLC. In reaction conditions suggested by Betsy Sutherland (personal communication), 33% of the dimers in the *E. coli* DNA were split but we observed no significant reduction in the relative quantity of 20-base material. Although this suggested that the ligating dimers were insensitive to the enzyme, the possibility remained that the 20-base oligonucleotides were too small for efficient substrate recognition. Competition experiments have shown that photolyase from yeast will efficiently recognize dimers on oligonucleotides 20 base pairs (bp) long[14]. To interpret our negative result unambiguously we needed to demonstrate that the *E. coli* enzyme also recognized dimers on small oligomers. In a series of competition experiments analogous to those performed with the yeast photolyase, we demonstrated that irradiated $oligo(d(pT)_{10}) \cdot poly(dA)$, containing photoligated oligonucleotides 20 bp long, did in fact compete with irradiated *E. coli* DNA for the *E. coli* photolyase. Thus, photolyase was able to recognize the dimers in photoligated oligonucleotides 20 bp long and possibly in even smaller oligonucleotides. As photolyase did not break the linkages, we concluded that the lack of a phosphodiester bond at such sites reduces significantly the activity of the enzyme.

Another enzyme that is specific for the cyclobutane pyrimidine dimer is endonuclease V from *E. coli* infected with bacteriophage T4[15]. This enzyme (T4 endo V) incises DNA containing pyrimidine dimers by a two-step process. First, a dimer-specific DNA glycosylase cleaves the 5′ pyrimidine of the dimer from its sugar and then an apyrimidinic–apurinic endonuclease cuts the phosphodiester linkage between the dimerized bases, leaving an apyrimidinic site at the 3′ end at the nick[3,16]. As there is no phosphodiester linkage between the thymidines in the ligating dimer, the action of the glycosylase alone should break the linkage. We wished to compare the glycosylase activity of T4 endo V on ligating dimers with that on internal dimers. We irradiated $d(pT)_{10} \cdot poly(dA)$ with long-wavelength UV to produce both internal and ligating dimers.

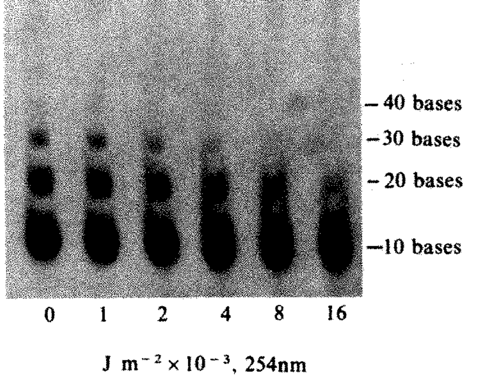

Fig. 3 Photoreversal of ligating dimers by 254 nm irradiation. $d(pT)_{10} \cdot poly(dA)$ was irradiated for 30 min with long-wavelength UV as described in Fig. 1 legend. The solution was then irradiated again at a distance of 10 cm from a 15 W mercury germicidal lamp whose principal output is 254 nm. At times corresponding to the doses shown, samples were removed and analysed by electrophoresis in the same conditions as before.

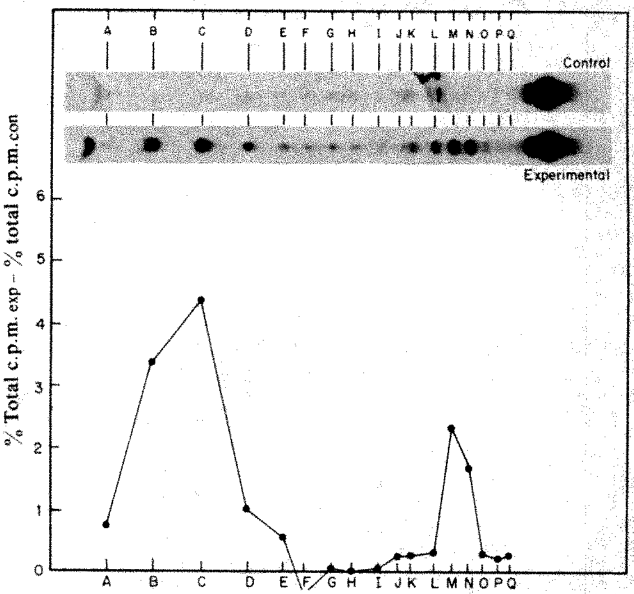

Fig. 4 Action of the glycosylase of T4 endo V on 20-base oligonucleotides containing a ligating dimer between the 10th and 11th positions. The top of the figure shows the electrophoresis patterns of photoligated oligonucleotides before and after treatment with T4 endo V and NaOH. The DNA moved from right to left. The very intense band at the origin represents the 20-base substrate and the bands to the left represent scission products of decreasing size. The top lane shows the pattern obtained for DNA treated with NaOH to hydrolyse the phosphodiester bond at apyrimidinic sites already present. The defect in the autoradiogram at the band labelled L was not the result of radioactivity in the gel. The bottom lane shows the pattern obtained for DNA that had been treated with T4 endo V followed by NaOH. Strand scissions occurred on both ends of the molecule (A–D and L–N). Although oligonucleotide markers were run in adjacent lanes (not shown), unambiguous assignment of lengths to each band was impossible, thus we have only lettered them. Action of the enzyme on the ligating dimer would have yielded a fragment migrating between I and K. Each band shown at the top of the figure was excised and assayed for radioactivity. After expressing the radioactivity of each band as a percentage of the total radioactivity in its lane, we subtrated the control values ($c.p.m._{con}$) from the experimental values ($c.p.m._{exp}$). No strand scissions occurred at the centre of the oligonucleotide although every molecule contained a ligating dimer at its centre. The substrate molecules for this experiment were isolated by electrophoresis (12% acrylamide, 7 M urea gel) of irradiated $d(pT)_{10} \cdot poly(dA)$ (20 min long-wavelength UV), followed by electroelution of the 20-base band. We 5′end-labelled these molecules with ^{32}P and precipitated them with ethanol. Enzyme reactions were carried out in 20 µl buffer (10 mM Tris, 10 mM EDTA, *p*H 8.0) at 37 °C for 30 min. NaOH was then added to 0.1 M and the samples were incubated at 90 °C for 30 min. After lyophilization the samples were resuspended in 5 µl formamide and run on a 20% acrylamide, 7 M urea gel[20].

After separation on a urea gel, we recovered the 20-base oligomers by electroelution and then ^{32}P-labelled their 5′ ends. Each 20-base oligonucleotide thus obtained contained a ligating thymine dimer between positions 10 and 11 and an average of one or two dimers randomly distributed over the other positions (except positions 9–10 and 11–12, which are prohibited in these molecules). The sample was then treated with excess T4 endo V, and heated in NaOH to ensure that strand scission would occur at all sites of glycosylase activity of the enzyme. A control sample was treated with NaOH after incubation without the enzyme. All enzyme reactions were performed on single-strand DNA to eliminate the possibility that denaturation differences between the locations of internal and ligating dimers might affect the results. The products of the reactions were analysed by electrophoresis on a 20% polyacrylamide DNA sequencing gel (Fig. 4); a band should appear for each dimer site sensitive to the enzyme plus NaOH. As there is a 100% probability of having a ligating dimer in the 10–11 position but a less than 10% chance of having an internal dimer at any other particular site, this experiment detects susceptibility of the linking dimer to the enzyme with a 10-fold greater sensitivity than that for internal dimers. Nevertheless, no breakage at the position of the linking dimers was detected (Fig. 4). In our laboratory it has been found that thymine dimers in $d(pT)_{17}$, treated in exactly the same manner, are sensitive to T4 endo V along the entire mid-section of the molecule (to be published), which excludes the possibility that the mid-section of an oligonucleotide is insensitive to the enzyme.

Thus, as was suggested with photolyase, the glycosylase activity of the T4 endo V seems to require a phosphodiester backbone. In this case, however, we demonstrated that internal dimers in our 20-base molecule were sensitive to the enzyme, while the ligating dimer was not. Proposed mechanisms for either enzyme must eventually take into account this feature of substrate recognition and action.

Could the pyrimidine dimer have served as a primordial 'ligase', linking short oligomers of nucleotides for the abiogenic assembly of high molecular weight duplex nucleic acids? In 1974 Tšo pointed out that in the laboratory "no satisfactory chemical synthesis of long-chain polynucleotides has succeeded under any conditions, prebiotic or otherwise"[17]. Since then, much progress has been made in template-directed non-enzymatic polymerization of nucleotide derivatives. For example, Zn^{2+} has been shown to serve as "an efficient catalyst for the oligomerization of guanosine 5'-phosphorimidazolide on a polycyticlylic acid template"[18].

Once high molecular weight polynucleotide templates existed, simple catalysts could make multiple complementary copies of them. But how did these templates originate and how did they increase in length? Small oligomers might have been created by a number of reactions: for example, condensation of 5' thymidine monophosphates by heating in the presence of histidine has been shown to yield oligomers up to 7 units long and containing predominantly the 3'–5' phosphodiester linkage[19]. The yields from such reactions fall off rapidly as the length of the oligomer increases, however, thus it is highly unlikely that the 'first' high molecular weight template formed exclusively by these reactions. Instead, we envisage the accumulation of overlapping oligomeric structures, followed by some ligation event(s) to generate much larger structures. This would occur simultaneously with template-directed polymerization reactions. The enhanced thermal stability of the larger duplex structures should help to drive the process forward.

The results presented here show that the ligation of short oligomers having thymidine nucleotides at their termini could have been accomplished by formation of cyclobutane pyrimidine dimers. In the primordial era there was no stratospheric ozone layer to attenuate the intense UV flux from the sun. Thus, it is fairly certain that pyrimidine-containing oligonucleotides accumulated dimers. We suggest that the cyclobutane pyrimidine dimer that poses a threat to DNA replication and survival in present day organisms, might have played a part in the prebiotic assembly of the first genetic material.

We thank Betsy Sutherland and Pat Seawell for supplying photolyase and T4 endo V, respectively; Ann Ganesan, Michel Philippe, Allen Smith and Mimi Zolan for support; and Evelyn Gates for repeatedly typing the text. This work was supported by a grant GM09901–20 from the National Institute of General Medical Sciences, USPHS.

Potential Z-DNA forming sequences are highly dispersed in the human genome

Hiroshi Hamada & Takeo Kakunaga

Cell Genetics Section, Laboratory of Molecular Carcinogenesis,
National Cancer Institute, NIH, Bethesda, Maryland 20205, USA

Recent analyses of the three-dimensional structure of synthetic DNA molecules has revealed the existence of a left-handed double-helical conformation of DNA, called Z-DNA[1–4]. The Z-DNA structure was first observed in molecules having alternating guanine and cytosine bases[1–3], but has now also been shown for molecules of sequence poly(dT-dG)·poly(dC-dA) (refs 4–7). If Z-DNA occurs naturally then it might have quite different reactivities with molecules such as proteins or carcinogens from right-handed B-DNA. The interconversion of sequences between B and Z forms, under the influence, for example, of DNA binding proteins or chemical modification, may be important in regulating DNA function[8,9]. So far, little data have been published on the occurrence of potential Z-DNA forming sequences in eukaryotic DNA. Here we report the presence of a sequence of 50 alternating dT and dG residues within one of the introns of a human cardiac muscle actin gene. Also, using a probe specific for poly(dT-dG) sequences, we have found that potential Z-DNA forming sequences are highly repeated in the human genome.

We have recently isolated a phage clone that contains a human cardiac muscle actin gene, λHa-25 (Fig. 1). This clone was obtained by screening of a human DNA library that had been constructed by partial *Eco*RI digestion of DNA from a β°-thalassaemia patient and ligation to Charon 4A phage vector[10]. The molecular structure (Fig. 1*a*) and nucleotide sequence of the entire coding region and some introns of the cloned cardiac muscle actin gene were determined[11]. In intron IV we found a sequence of 25 alternating dT and dG residues (abbreviated to $(dT\text{-}dG)_{25}$). Figure 1*b* shows the nucleotide sequence of the intron IV–exon 5 boundary region. The presence of $(dT\text{-}dG)_{25}$ near the intron–exon junction was confirmed by sequencing of both DNA strands by the Maxam–Gilbert method. The repeated sequences found are not an artefact of our cloning procedure because we used $RecA^-$ mutant *Escherichia coli* as a host, and we have further been able to isolate human cardiac muscle actin gene with exactly the same restriction map as that of λHa-25 by screening a second human DNA library constructed by partial *Eco*RI digestion of DNA from a chemically transformed human fibroblast cell line (our unpublished data). Our finding of a $(dT\text{-}dG)_{25}$ stretch is a direct demonstration of potential Z-DNA sequences in the eukaryote DNA. If poly(dT-dG) sequences are functionally important then it is to be expected that they should be found in other parts of the genome. To examine this possibility we carried out the following two Southern blotting analyses. In the first analysis we used ^{32}P-labelled total DNA from human HeLa cells on a probe to detect repeated sequences in the *Eco*RI–*Bam*HI 8-kilobase (kb) fragment of the λHa-25. In this method only

Fig. 1 *a*, Molecular organization of the human cardiac muscle actin gene. The black blocks show the locations of six exons. The arrow above the map indicates the direction of transcription. Six exons and five introns are designated from 1 to 6 and from I to V, respectively, according to their locations. The hatched blocks show the presence of three different repeated elements. These locations were determined by hybridization to ^{32}P-labelled total human DNA or ^{32}P-labelled cloned human *Alu* family (provided by Dr Schmid) (data not shown). *b*, Nucleotide sequences of intron IV–exon 5 boundary region. DNA sequence was determined by the Maxam–Gilbert method[21]. The vertical arrow indicates the splicing site. *Alu*I site in intron IV is enclosed by a box. The sequence (dT-dG)$_{25}$ is underlined. The amino acid sequence corresponding to DNA sequence of exon 5 is shown under the nucleotide sequence.

highly repeated (>100 copies per cell) sequences are detected. When the 8-kb *Eco*RI–*Bam*HI fragment was digested with *Pst*I a 0.9-kb band hybridized to the probe (Fig. 2). A probe specific for the *Alu* family of repetitive sequences[12] did not hybridize to any region of the *Eco*RI–*Bam*HI fragment (data not shown). The 0.9-kb fragment contains all of exon 5 and a part of introns IV and V. In order to narrow further the location of the repeated element, we constructed a subclone of the 0.9-kb *Pst*I fragment in pBR322. By Southern blotting analysis of restriction digested 0.9-kb DNA fragment using ^{32}P-labelled total human DNA as a probe, the repeated element was mapped between the *Alu*I site in intron IV and *Sau*96I site in exon 5 (Fig. 2). As the actin-coding sequence is not highly repeated in the human genome, we conclude that a highly repeated element is located in the 110-base pair (bp) region between the *Alu*I site in intron IV and the 5′ splicing site—precisely the region where (dT-dG)$_{25}$ is located.

In the second analysis, the DNA used as a probe, and that probed were reversed. ^{32}P-labelled 0.9-kb *Pst*I fragment was used as a hybridization probe against *Eco*RI-digested human DNA. As shown in Fig. 3*a* a smear of hybridization was observed with the HeLa DNA, indicating again that the 0.9-kb *Pst*I fragment contains the highly repeated element. To demonstrate that the repeated element in the 110-bp region between *Alu*I site and splicing site is the sequence (dT-dG)$_{25}$, we prepared ^{32}P-labelled poly(dT-dG) · poly(dC-dA) as a probe to specifically recognize sequences. The specificity of the probe was confirmed by the exclusive hybridization of the probe to (dT-dG)$_{25}$-containing fragments when hybridized to restriction enzyme digested λHa-25 DNA (Fig. 3*b*). This probe also produced a smear of hybridization in gels containing *Eco*RI-digested total human DNA (Fig. 3*b*), thus indicating that (dT-dG)$_n$ is a repeated element. We also determined the copy number of (dT-dG)$_n$ sequences in the human genome by Dot analysis[13], using the (dT-dG)$_n$-specific probe (Fig. 4). The approximate number of (dT-dG)$_n$ copies was estimated as 10^5 per human genome, assuming that the average size of n is 25.

These results clearly indicate the widespread distribution in the human genome of sequences that cross-hybridize with the poly(dG-dT) · poly(dA-dC) probe. The following observations suggest that most of the hybridizing sequences are poly(dT-dG) stretches. First, the hybridization conditions used were so stringent that the sequences containing more than 15% of mismatched nucleotide sequence would not cross-hybridize with the probes. Second, large excess amounts of *E. coli* DNA did not compete at all with the probes for hybridization to human DNA. Third, sequence analysis of one of hybridizing clones containing *Eco*RI-digested human DNA proved to contain an exact (dT-dG)$_{15}$ sequence (unpublished data). Fourthly, a (dT-dG)$_{17}$ sequence has been found in human globin genes[14]. The observation that our probe did not hybridize to pBR322 DNA (data not shown), which contains a (dT-dG)$_3$ sequence indicates that the DNA fragments that cross-hybridized to the probe contain a significant stretch of alternating dT and dG residues.

It has been reported that the C(8) position of deoxyguanosine residues, which is the primary position of binding of mutagens and carcinogens such as *N*-acetoxy-*N*-2-acetylaminofluorene (*N*-AcO-AAF), is exposed on the outer surface of the DNA molecules in Z-DNA but not in B-DNA. *N*-AcO-AAF modification or methylation of cytidine in the 5-position in poly(dG-dC) · poly(dG-dC) has been found to favour the transition of the polymer from the B to Z conformation[15–17]. Mutational 'hot spots' have been shown to exist in the *hist D* gene of *Salmonella*, within which is a (dG-dC)$_4$ sequence[18]. Further, cloned segments of poly(dG-dC)$_{13}$ · poly(dG-dC)$_{13}$ in a plasmid undergo a B to Z transformation even though they are enclosed in plasmid segments containing B-DNA[19]. Nordheim *et al.* recently reported that antibodies specific to the Z-DNA conformation bind to interband regions of *Drosophila* polytene

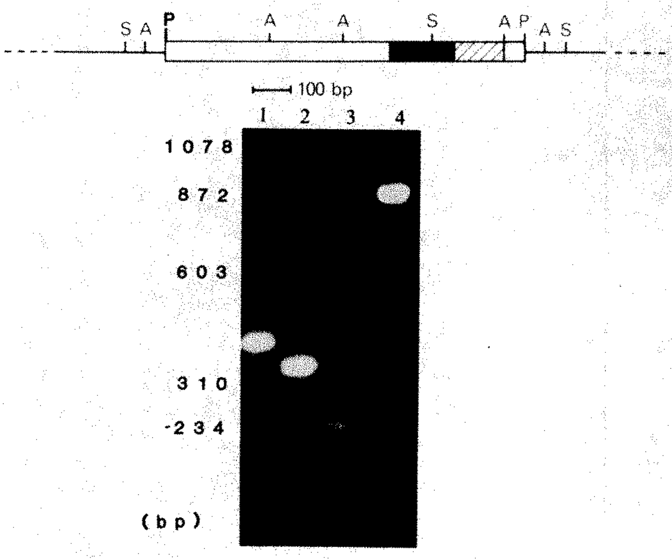

Fig. 2 Mapping of highly repeated sequences in human cardiac muscle actin gene. pEB 8.0 DNA, a subcloned DNA containing the *Eco*RI–*Bam*HI 8-kb fragment in pBR322, was digested with *Pst*I (lane 4). pPst 0.9-1 DNA, constructed by subcloning of the *Pst*I 0.9-kb fragment shown in Fig. 1 into pBR322, was digested with *Alu*I (lane 1), *Sau*96I (lane 2), or *Sau*96I and *Pst*I (lane 3). The resulting DNA fragments were separated on a 2% agarose gel, transferred to nitrocellulose filter, and hybridized to total HeLa cell DNA labelled with ^{32}P by nick-translation. Hybridization was carried out as described previously[22]. *E. coli* DNA was used as carrier DNA. The filter was washed in 1×SSC 0.1% SDS at 50 °C three times and in 0.1×SSC 0.1% SDS at 50 °C twice. The restriction map of pPst 0.9-1 DNA is shown above the autoradiogram. The solid and broken lines indicate pBR322 DNA. The box indicates the 0.9-kb *Pst*I fragment subcloned into pBR322. The black box and open boxes denote coding region and introns, respectively. The hatched region shows the location of the repeated sequence as determined by the results shown in this figure. The arrow above the map indicates the direction of transcription. The restriction enzyme sites are abbreviated as the following: A, *Alu*I; P, *Pst*I; S, *Sau*96I. *Hae*III digests of ΦX174 DNA served as a molecular size standard.

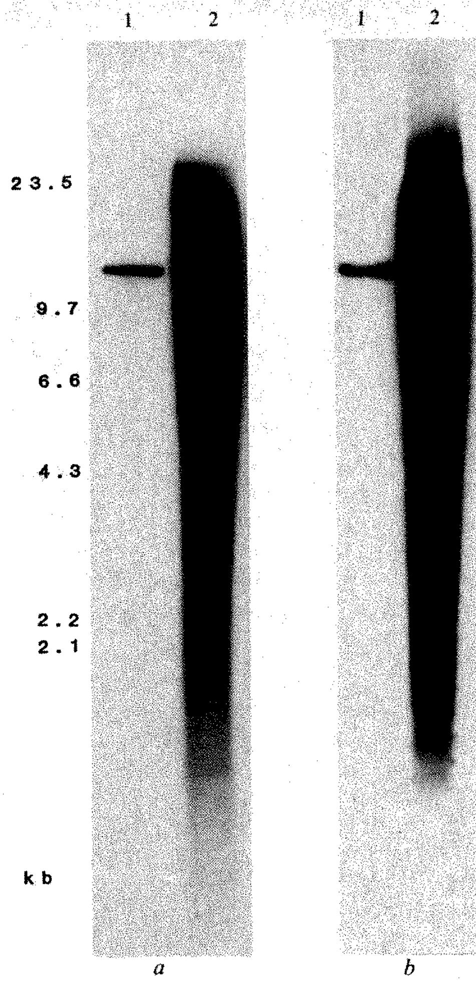

Fig. 3 Detection of poly(dT-dG) sequences in a human genome by Southern blot hybridization. 20 μg of HeLa cell DNA was completely digested with *Eco*RI (lane 2 in *a* and *b*). Fifty copies equivalent (lane 1 in *a* and *b*) amount of λHa-25 DNA was digested with *Eco*RI. These equivalent amounts were calculated based on the assumption that human genome size is 3×10^9 bp, and our data that $(dT\text{-}dG)_{25}$ exist only once in λHa-25 (data not shown). The resulting DNA digests were electrophoresed on 0.7% agarose gel, transferred to nitrocellulose filter and hybridized to ^{32}P-labelled probe. Hybridization was carried out as described above. The probes used here are nick-translated *Pst*I 0.9-kb fragment in *a* and nick-translated poly(dT-dG)·poly(dC-dA) in *b*. The latter probe was prepared by annealing of $(dT\text{-}dG)_{6-9}$ and $(dC\text{-}dA)_{6-9}$ (Collaborative Research) followed by nick-translation.

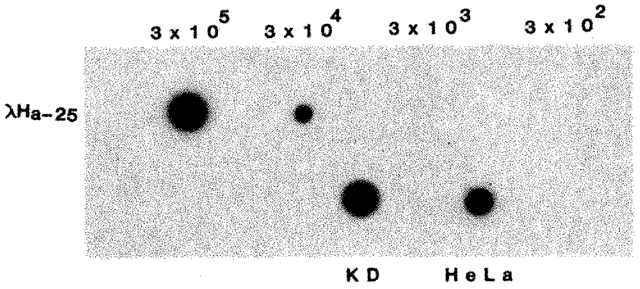

Fig. 4 Determination of copy number of poly(dT-dG) sequences in human genome. 0.25 μg of human DNA prepared from HeLa cell or KD cell (normal diploid human fibroblast) and 3×10^5, 3×10^4, 3×10^3 or 3×10^2 copies equivalent amount of λHa-25 DNA were denatured and spotted on nitrocellulose filter as described by Kafatos *et al.*[13]. These equivalent amounts were calculated as described above. The filter was hybridized to ^{32}P-labelled poly(dT-dG)·poly(dA-dC) as described above.

chromosomes[20]. It is plausible that a portion or all of the $(dT\text{-}dG)_n$ sequences that we have found to be highly dispersed in the human genome adopt a Z conformation depending on the circumstances and that these sequences may be important in mutagenesis, recombination and the control of gene expression.

We thank Dezider Grunberger and Che-Hung Lee for their valuable suggestions and Kenneth H. Kraemer for his help with and Linda Nischan for typing the manuscript.

McMaster University, Hamilton, Ontario, Canada L8N 3Z5

A wide range of receptors are located at the blood sinusoidal aspect of the hepatocyte plasma membrane[1,2]. Many circulating ligands that bind to receptors on the cell surfaces are interiorized along two pathways. Asialoglycoproteins[3] are transferred from the plasma membrane to lysosomes and degraded, whereas immunoglobulin A[4] and bile acids[5] are transported across the hepatocyte interior and released into bile. Asialotransferrin type 3 (ref. 6) follows a further pathway termed diacytosis[7]. After binding to the asialoglycoprotein receptor[8], asialotransferrin is endocytosed and then returned to blood with a proportion of its carbohydrate side chains resialylated[9]. We now describe in liver the properties of intracellular asialotransferrin-enclosing vesicles (diacytosomes) and show that they differ from Golgi, lysosome and plasma membrane fractions. Furthermore, we show that the asialoglycoprotein binding sites are located on the cytoplasmic (outer) surface of diacytosomes.

Asialotransferrin, after binding to the hepatic asialoglycoprotein receptor[3,10–13], is rapidly interiorized. Analytical centrifugation of liver homogenates in sucrose gradients shows that within 5 s of injecting asialotransferrin into the liver via the portal vein, the ligand equilibrates at a density corresponding to plasma membranes (1.16 g cm^{-3}) and then moves rapidly, through an intermediate density (1.13 g cm^{-3}) at 30 s, to a final density position of 1.10–1.11 g cm^{-3}, where it remains intact for long periods[14]. The components equilibrating at the latter

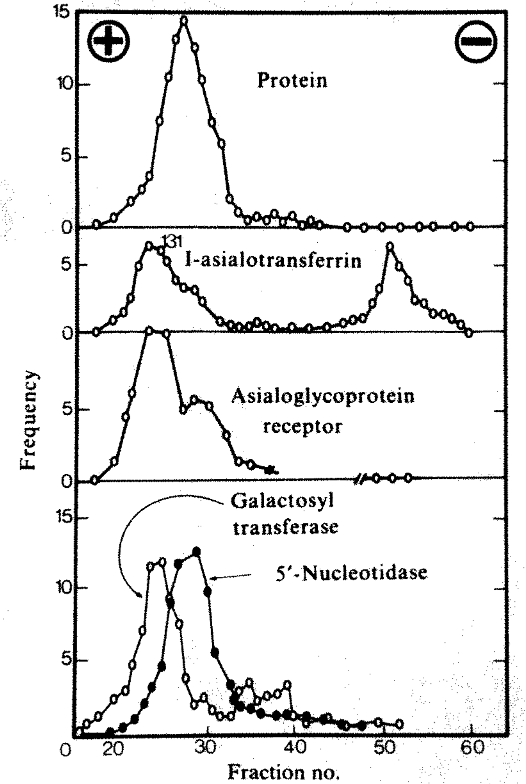

Fig. 1 Fractionation of the diacytosome fraction, prepared as described in Table 1 legend, by free-flow electrophoresis in an Elphor VaP5 apparatus (Bender and Hobein, Munich). The conditions used were essentially as reported by Menashi *et al.*[34]. Protein was determined by the microtannin turbidometric method[31], and asialoorosomucoid binding by the Pricer and Ashwell method[32]. Galactosyl transferase and 5'-nucleotidase activities were determined by standard methods[35]. The results are expressed as the frequency of distribution of components recovered from the apparatus from livers 15 min after administration of ^{125}I-asialotransferrin.

Table 1 Recovery and relative specific activities of radioiodinated ligands and marker enzymes in the diacytosome fraction

Component in diacytosome fraction	% Recovery from homogenate	Specific activity relative to homogenate
Protein	0.25 ± 0.04 (4)	—
Asialotransferrin type 3	19.4 ± 0.9 (4)	62.0
Asialoorosomucoid	2.7 (2)	6.5
Insulin	7.9 ± 1.1 (4)	25.0
Galactosyl transferase	21.0 (2)	65.0
Sialyl transferase	9.5 (2)	51.0
5'-Nucleotidase	6.7 ± 2.4 (4)	16.5
Alkaline phosphodiesterase	2.5 ± 0.4 (4)	6.5
Acid phosphatase	1.0 (2)	2.2
β-galactosidase	0.09 (2)	0.1

Diacytosomes were prepared from unstarved rat liver homogenates as described in detail elsewhere[22]. Briefly, nuclei, mitochondria and lysosomes, plasma membranes and Golgi components of livers homogenized in 0.25 M sucrose were removed by centrifugation sequentially at 1×10^4g min and 4×10^5g min. The final clear supernatant was centrifuged into a 10–40% w/v sucrose gradient at 97,000g_{av} for 4 h (Beckman SW27 rotor) and components equilibrating at densities of 1.097–1.117 g cm^{-3} were pooled and concentrated by vacuum dialysis. Radioactivity and enzymes (70–90%) and a protein peak (20–25%) were eluted in the void volume peak of a Sepharose 2B column equilibrated in 10 mM Tris-HCl *p*H 7.4, 1 mM EDTA and 0.15 M NaCl, and concentrated by centrifugation. The three ligands were iodinated using the iodogen method[36]. Asialotransferrin type 3 (5 μg), asialoorosomucoid (20 μg) or insulin (20 μg) were injected intraportally into rats (150 g body weight) and livers removed and homogenized 10–15 min later when most of the asialotransferrin and proportions of asialoorosomucoid and insulin equilibrated in the density range 1.095–1.12 g cm^{-3}. Enzyme activities and radioactivity were determined as previously described[14,15,24]. The complete distribution of all components in the fractions will be described elsewhere[22], and total recoveries were 89–103% of homogenate values. Standard errors of the mean and the number of experiments (in parentheses) are given.

density were isolated in a subcellular fraction now operationally defined as the diacytosome fraction, using a modified method for preparing blood sinusoidal plasma membranes[15]. The diacytosome fraction was obtained (Table 1) by centrifuging the homogenate supernatant in a continuous sucrose gradient after pelleting nuclei, plasma membranes, mitochondria, lysosomes and Golgi apparatus components. Soluble proteins associated with the diacytosome fraction were removed by permeation chromatography. The diacytosome fraction retained about 20% of the bound ^{125}I-labelled asialotransferrin and 10–20% of homogenate glycosyl transferase activities (Table 1); recovery of 5'-nucleotidase and alkaline phosphodiesterase was lower and more variable, and that of lysosomal enzymes very low.

On further resolution of the diacytosome fraction by free-flow electrophoresis[16] (Fig. 1), although a single protein peak emerged, the galactosyl transferase and residual 5'-nucleotidase activities separated into adjacent peaks. Importantly, however, the positions of the major asialotransferrin peak, the major peak representing asialoglycoprotein receptor-binding activity and the galactosyl transferase coincided. Although this result could have implied that asialotransferrin was interiorized to the Golgi apparatus, the morphological features and the ligand–receptor binding properties of diacytosomes showed that the recovered ligand resides in previously undocumented subcellular components.

Examination of the diacytosome fraction by electron microscopy showed a relatively homogeneous population of smooth-surfaced vesicular profiles, 600–1,200 Å in diameter. The cisternal tubular networks and vaculoles characteristic of Golgi apparatus fractions[17–19] were rarely seen. No coated vesicles[20] were detected, even when negatively stained preparations were examined. Fractions containing the ligands, receptors and galactosyl transferase (Fig. 1) contained a higher proportion of vesicles with single or compound intraluminal vesicular membrane components (Fig. 2). Similar vesicles were present as minor components in gross Golgi[17–19] and plasma membrane sinusoidal fractions[15] prepared from liver. Recently, similar multi-vesicular structures (termed 'receptosomes', although no receptors or receptor binding was measured) were described in cells that have interiorized ligands[21].

Table 2 shows that the diacytosome fraction has a much higher capacity for binding asialoglycoproteins than do the plasma membrane and Golgi subfractions. Examination of the orientation of the receptors on the vesicles by measuring the binding capacity of various fractions after treatment with Triton X-100 showed that the binding capacity of the Golgi subfractions increased two- to three-fold, indicating that most of the receptor sites were located inside the membrane-enclosed

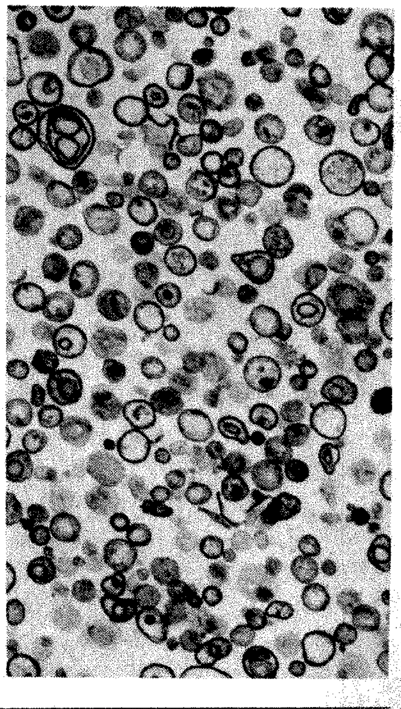

Fig. 2 Electron micrograph of fraction 23 from the free-flow electrophoresis separation (Fig. 1). Membranes were concentrated by centrifugation on to a 51% (w/v) sucrose cushion, and sections prepared for viewing by standard methods[15]. ×27,800.

Table 2 Effects of treatment with Triton X-100, trypsin and sonication on binding of asialoorosomucoid and insulin to diacytosome, Golgi and plasma membrane fractions

Fraction	Specific binding activity						
	Asialoorosomucoid (ng per μg protein)						Insulin (ng per mg protein)
	No treatment	0.1% Triton X-100	Sonication	Trypsin	Trypsin and sonication	Trypsin and 0.1% Triton X-100	
Diacytosome	6.1 ± 0.4	5.6 ± 0.6	6.2 ± 0.3	0.03 ± 0.01	0	0.05 ± 0.01	1.14 ± 0.11
Golgi—heavy	0.9 ± 0.2	2.7 ± 0.2	3.1 ± 0.1	0.17 ± 0.1	2.3 ± 0.6	3.3 ± 0.3	0.27 ± 0.02
Golgi—intermediate	0.8 ± 0.1	2.5 ± 0.6	—	—	—	—	0.57 ± 0.09
Plasma membrane (heavy)	1.4 ± 0.2	1.7 ± 0.3	—	—	—	—	0.71 ± 0.02
Plasma membrane (sinusoidal)	2.2 ± 0.3	2.7 ± 0.1	1.6	0.10	0.24	0.03	0.39 ± 0.02

The diacytosome fraction was prepared as described in Table 1 legend, and Golgi and plasma membrane fractions by standard procedures[15,18]. Asialoorosomucoid binding was carried out as described by Pricer and Ashwell[32], and insulin binding as described previously[33]. Sonication of membrane fractions was carried out in a Sonic Dismembrator (Fisher, Model 300) using 2 × 10 s bursts at setting '35'. Trypsin treatment was carried out before binding studies as follows. Membrane fractions (250 μg protein) were incubated for 15 min at 23 °C with trypsin (250 μg; P–L Biochemicals); control samples were incubated in the buffer 0.15 M NaCl, 0.005 M $CaCl_2$ 0.01 M Tris-HCl *p*H 8. Protease treatment was stopped by addition of a fivefold (w/w) excess of crystalline soybean trypsin inhibitor (Worthington). In separate studies, the trypsin inhibitor had no effect on ligand binding. Values are shown ± s.e.m. of three to five determinations.

compartments. In contrast, no increase in binding capacity was elicited by detergent treatment of the diacytosome fraction, thus indicating that the binding sites were located on the outer surface. Further evidence for an external location of the asialoglycoprotein receptor on diacytosomes was obtained by the finding that sonication had little effect on asialoorosomucoid binding by the diacytosome fraction, whereas a three-fold increase, similar to that elicited by treatment with Triton X-100, was obtained with a Golgi fraction. Trypsin treatment removed 96% of the asialoorosomucoid binding capacity of diacytosomes when carried out alone or in combination with sonication or exposure to Triton X-100, two treatments that should reveal any additional receptors located inside the vesicles. On the other hand, the diminution in binding capacity of the Golgi fraction occurring after trypsin treatment was low when compared with that measured after sonication or Triton X-100 treatment. These results provide strong evidence that the receptor-binding sites are located mainly on the outer (cytoplasmic) surface of the diacytosome.

A role for diacytosomes in the receptor-mediated uptake of insulin was also briefly investigated, for about 8% of the ^{125}I-labelled insulin associated with particulate components of the liver homogenate 10–15 min after injection was recovered in the diacytosome fraction (Table 1). Comparison of the insulin-binding capacity of the diacytosome with plasma membrane and Golgi fractions showed that diacytosomes possessed the highest activity (Table 2), and preliminary observations suggest that a proportion of the insulin receptors is cytoplasmically orientated.

The morphology, high concentration and external orientation of receptors, when taken with the simplified polypeptide composition relative to plasma membrane and Golgi fractions[22], indicate that diacytosomes cannot be categorized directly into the major hepatic classes of subcellular organelles and membrane systems described[23,24]. However, in view of the structural and functional complexity of the Golgi apparatus, especially in secretory tissues[25] the vesicles may originate from a region of the Golgi apparatus specialized for the processing of classes of ligands internalized by hepatocytes. A diacytotic pathway along which ligands move in and out of the hepatocyte can be divided into inward (endocytotic) and outward (exocytotic) sector legs. The association of glycosyl transferases with the diacytosome fraction indicates that the more electronegative vesicles separated by free-flow electrophoresis may arise from components comprising the intracellular terminus of the diacytotic pathway. The glycosyl transferases in the diacytosome fraction can also explain the glycosylation of internalized asialotransferrin demonstrated in *in vivo* experiments[9].

Finally, the cytoplasmic orientation of asialoglycoprotein receptors demonstrated on the diacytosomes indicates that the receptor–ligand complex formed at the plasma membrane has been rearranged during internalization. Either there is receptor reorganization in the membrane lipid bilayer[26], or engulfment of membrane components of the inward sector leg and multiple fusions have taken place, resulting in a dissociation of the complex with the receptors now becoming cytoplasmically orientated. Indeed, these results add to the increasing indirect evidence for discrete intracellular compartments bearing cytoplasmic receptors for lectins[27], phosphomannosyl enzyme[28], asialoglycoproteins[29] and human growth hormone[30]. External receptors on diacytosomes, while undoubtedly contributing to their high electronegativity exploited in the free-flow electrophoretic separation, may provide recognition potential ensuring specificity in the vesicular transport of ligands inside the cell. The high concentration of receptors on diacytosomes suggests a role in receptor recycling and therefore receptor turnover at the plasma membrane.

We thank Professor Neville Crawford and Dr Donald Stuart, Institute of Basic Medical Sciences, Royal College of Surgeons, London for their help and support in running the free-flow electrophoresis apparatus, and Miss Kate Sullivan for electron microscopy. Part of this study was supported by the MRC of Canada and the Ontario Heart Foundation.

MATTERS ARISING

Dielectric constant of ice

ADAMS has recently considered the dielectric constant of ice[1]. His Monte Carlo calculations fill a gap in the literature and complement previous calculations. However, his theoretical discussion, while displaying an important constraint on the Kirkwood–Frohlich (K–F) theory, falls short of the 'simple resolution' claimed.

Adams' primary equation[1] is

$$\langle \mu_1 \Sigma \mu_i \rangle_{\varepsilon'} N/9\varepsilon_0 kTV = (\varepsilon - 1)(2\varepsilon' + 1)/3(\varepsilon + 2\varepsilon') \qquad (1)$$

The right hand side (RHS) of equation (1) is obtained using macroscopic electrostatic theory for a spherical system of ice of dielectric constant ε surrounded by a much larger sphere of dielectric constant ε'. The left hand side (LHS) of equation (1) is obtained using microscopic statistical mechanics for a system of water dipoles in the central sphere which interact with each other as well as with the material in the outer sphere, whence the subscript ε'. The internal field E_{int} which acts on the dipoles in the calculation of the LHS of equation (1) is interpreted to be the cavity field which would have existed if the ice sphere were removed, whereas the polarization P is computed from the field actually present in the electrostatic calculation before the ice sphere is removed. The first problem is to determine specifically which intermolecular interactions are required in the calculation of the LHS to make it correspond to the RHS for which the cavity field is used. This has not been *a priori* obvious as evidenced by the fact that several researchers[1–7], including Adams, have performed calculations assuming only short range interactions which Adams correctly concludes is an inconsistent model in the context of equation (1).

For the ideal ice-rules model the numerical results for the correlation sums g_K and G for the LHS appear to agree with the RHS for the respective cases of $\varepsilon' = \varepsilon$ and $\varepsilon' = \infty$. However, as Adams acknowledges, for a finite concentration of Bjerrum defects, which is a necessary feature of real ice, equation (1) becomes inconsistent because statistical mechanics requires that the two correlations sums G and g_K are equal when the ideal ice rules are broken and only short range interactions are included. Adams tries to eliminate this dilemma by the proposal that dipolar interactions, previously left out of all but one primitive calculation[8], will restore the numerical values of G and g_K to those given by the ideal ice-rules. As Adams admits, this proposal cannot be exact because the ice rules determine G/g_K to be independent of the dipole moment and temperature which cannot be true for dipolar interactions. He also admits that dipolar interactions are likely to raise the numerical value of G which would reduce the calculated dipole moment below the value $\mu = 3.0$ D quoted in his paper. Therefore, Adams' simple resolution leaves us with a theory for which neither G nor g_K has been calculated and for which such calculations may be practically impossible due to the difficulty of doing statistical mechanical calculations on systems with long range dipolar interactions. Adams' real conclusion, also emphasized by Stillinger[10], is that G and g_K must satisfy a relation (Adams' equation (9)) if the proper interactions consistent with the internal cavity field are included in the calculation of the LHS of equation (1).

Adams' theory is essentially an extension of the K–F theory to include the cases $\varepsilon' \neq \varepsilon$ and this allows him to connect the K–F equation, given by equation (1) when $\varepsilon' = \varepsilon$ for which the LHS has a factor g_K, to an equation which is derived from equation (1) by setting $\varepsilon' = \infty$ for which the LHS has a factor which Adams identifies as G. If this last identification is made, then the Onsager–Slater (O–S) equation is recovered and must be equivalent to the K–F equation because they both come from the same unified derivation. However, this identification is incorrect because to calculate the G required by Adams' theory it is necessary to include dipolar interactions; in contrast dipolar interactions are completely absent in the calculation of G appropriate for the O–S theory. This astonishing feature has caused many to dismiss the O–S theory too lightly. However, elsewhere I have shown that the O–S theory consists of a renormalization of the electrostatic interactions in ice into a dipole-free effective Hamiltonian[9]. Therefore, the G required for the O–S theory cannot be the same as the quantity required for the LHS of equation (1) which should henceforth be called by a different name, $g_{\infty=\varepsilon'}$. It then follows that the use of equation (1) does not permit a derivation of the O–S theory which is fundamentally different from the K–F theory[2,3,9]; in particular, the internal field in the O–S theory is not the cavity field. A major advantage of the O–S theory to the K–F theory is that extant calculations of G, which do not include dipolar interactions, can be applied immediately and unambiguously to the O–S theory. However, it is to be hoped that the more difficult calculation of g_∞ necessary for the K–F theory may also be performed and that this might indeed result in complete resolution of the theory of the dielectric constant of ice.

ADAMS REPLIES—The 'simple resolution' which I claim is the observation that it is not necessary to choose between either the Onsager–Slater equation or the Kirkwood equation. The Onsager–Slater equation, $\varepsilon - 1 = 3yG$, becomes equivalent to the exact Kirkwood equation when G is identified with g_∞ which is obtained with $\varepsilon' = \infty$ (that is, the 'tin-foil' case) and when all the dipole–dipole and other interactions of the model hamiltonian are included in the calculation[1,2]. The approximation of the Onsager–Slater theory is that the dipole–dipole interactions are to be ignored in the calculation of G.

Perfect ice-rules ice is a very simple hamiltonian which despite having no dipole–dipole interactions produces long-range dipole–dipole correlations of the sort to be expected in real dielectrics. I have calculated unambiguous values of $G = g_\infty$ and g_K for this model. The identification of such a model with real ice must be done with caution and I have tried to make an informed guess as to the direction of the error. One major approximation of the model is that all configurations allowed under the ice rules have the same energy. This cannot be too drastic an approximation or the observed residual entropy of ice would not be predicted so well.[3]

The other major approximation I have made is to ignore the Bjerrum defects which undoubtedly occur in real ice. However, when non-interacting defects are introduced into the model then the long-range correlations are destroyed and $g_K = G = g_\infty$ which cannot be true for a real dielectric. I argue that to introduce defects without also including the long-range electrostatic interactions which occur in all real dielectrics is to make the model worse and not better. I agree with Nagle that complete resolution requires making difficult calculations with all electrostatic interactions included and using the formally exact expressions for the dielectric constant of the Kirkwood type.

Body temperature changes during the practice of g Tum-mo yoga

IN their recent letter[1], Benson *et al.* do not provide sufficient information to determine whether the temperature changes reported indeed resulted from the practice of yoga. The 'control' time shown on their graphs ranged from 5 to 10 min, and significant fluctuations in temperature appeared to occur within even that brief time. For example, if the 1 °C change in finger temperature recorded during this time for the first subject, V.G.J., were extrapolated for the 55-min meditation period, a temperature change of ~5 °C would result, which represents most of the reported effect of 5–9 °C. The change in the toe temperature was even greater than the finger temperature change during the 'control' period.

I would like to see results of tests on non-meditating individuals, and on those individuals studied, to determine how their temperatures vary over periods of 1–1.5 hours, corresponding to the duration of meditation. I would also want experiments to be performed in a temperature controlled environment, as I suggest that room temperature changes of 2 °C, such as occurred during the trial of the second subject, could lead to greater changes in the temperature of the extremities.

1. Benson, H. *et al. Nature* **295,** 234–236 (1982).

BENSON *ET AL.*[1] present an interesting account of three persons who increase their finger and toe temperatures apparently by a Tibetan Buddhist meditational practice known as g Tum-mo (heat) yoga. To ensure that any observed changes in body temperature are directly attributable to this method of meditation, the use of a control group is desirable. As this study did not include a control group, it is possible that the observed effects were the result of some other factor, for example: (1) changes in the ambient air temperature (as was the case for two of the subjects, A and B, in this investigation); (2) the consumption of certain food known to increase metabolic activity; and (3) the placement of toe and fingers during the meditation and recovery period, for example, if toes or fingers were placed in an axillary cavity, this would effect a rapid rise in temperature. In addition, the location and method of attachment of the disk thermistors may be partly responsible for the changes in temperature. Further investigation should include the use of matched controls; possibly additional practitioners of g Tum-mo yoga could be used if they were willing to refrain from meditating during the testing period.

BENSON REPLIES—With regard to the comments of Strassburg and Pasachoff, the subjects in our experiment served as their own controls in an 'off–on–off' design. As the studies were performed in the isolated, mountain hermitages of the monks, it was not feasible to control the ambient temperature. The monks could not serve as their own matched controls at a later time because they would involuntarily lapse into g Tum-mo meditation while sitting quietly for prolonged periods, as we described for subject L.T. Closely-matched, simultaneously-studied controls would have been desirable, but this was not possible in a small Himalayan hut. Despite the changing ambient temperatures and lack of between-subject control, we believe the reported results are valid for the following reasons.

It is unlikely that the reported increases in skin temperature could have occurred spontaneously. Our study was performed in relatively cold to cool ambient temperatures[1]. There are two major modes of preserving body temperature in humans at cool ambient temperatures: heat conservation and increased heat production[2]. In the first adaptation, heat flow from the body centre to the skin is reduced through vasoconstriction of the arterioles in the skin. Thus, less heat is lost to the environment, but at the expense of decreased skin temperatures. When a comfortably warm individual enters an ambient temperature of 25 °C and does not change clothing or activity, his mean body skin temperature can decrease from ~33 °C to 31 °C, and heat loss to the environment is reduced by ~25%. Since the fingers and toes are thin cylinders with little mass in which to store heat, their temperatures usually decrease more, and much more rapidly, than those of the thorax and abdomen. Ordinarily, finger temperatures in environments such as those of our experiment are ~4 °C higher than ambient[3]. During the meditation period, however, the subjects' finger temperatures were 10–14 °C higher than ambient temperatures. The finger temperatures during the control period were already higher than expected. If the increases were spontaneous shifts, one would expect a return to normal, not a further deviation. In the second adaptation, the metabolic rate increases, and more heat is produced. Although it is possible that these men had learned to increase their metabolism to produce more body heat, this is also unlikely. Meditation practices generally have been associated with decreased metabolic rates[4]. Furthermore, the subjects' heart rates were within normal limits and relatively stable throughout. An increased heart rate would be expected in conditions of increased metabolism.

Pasachoff extrapolated several of the increasing, control-period temperatures of subject G.J; he disregarded those of the other subjects which were either stable or decreasing. Both Strassburg and Pasachoff mention the changing ambient temperatures as a possible confounding influence. There was, however, no consistent relationship between the temperature changes in the air and those of the skin of the subjects. For example, in G.J., the finger and toe temperature increases preceded the increases in air temperature; his finger temperature returned to baseline when ambient temperature was highest. In L.T., finger temperature increased during the meditative period at a time when ambient temperature was decreasing. As for the possibility that the location and method of attachment of the thermistors may have been partly responsible for the temperature changes, the thermistors were placed at representative skin sites of the thorax, abdomen and extremities and remained closely taped to the skin during each experiment. Both increases and decreases in skin temperature were recorded. Although there may have been some damping of the magnitude of the observed alterations in temperature, the method of application of the thermistors did not inhibit the decreases during the recovery period.

Finally, Strassburg mentions that placement of toes or fingers in an axillary cavity would bring about a rapid rise in temperature. This is true, but the subjects were under constant observation by four people throughout the experiments and assumed no such position. It is intriguing, however, to contemplate the resulting posture with one's toes in one's armpits or, perhaps, in someone else's armpits?

BOOK REVIEWS

A kind of anthropology

R.D. Attenborough

Social Anthropology. By Edmund Leach. Pp.254. Hbk ISBN 0-19-520371-0; pbk ISBN 0-00-635533-1. (Oxford University Press/Fontana: 1982.) Hbk £9.50, $17.95; pbk £2.50.

FOR ALL his eminence, Professor Sir Edmund Leach apparently does not anticipate much critical acclaim for his contribution to Fontana's new *Masterguide* series. As he writes in the introduction, the book is not addressed to his anthropological colleagues,

> many of whom are likely to be contemptuous of the style of anthropology which it advocates, and which they may well denounce as old-fashioned, egocentric, unscientific, escapist, lacking in coherence, political commitment and so on.

So readers are forewarned of an unfavourable reaction among social anthropologists, which does indeed seem to be emerging, though not entirely on the grounds predicted (see the review by Maurice Bloch, *Times Literary Supplement*, April 16). As a biological anthropologist offering a view from just outside the subject, I differ in perspective but have arrived independently at partly similar conclusions.

Leach's intention in this book is quite expressly to write about "my kind of anthropology", and accordingly the unabashed pursuit of his own intellectual concerns is evident throughout. This strongly personal flavour has its drawbacks, in that the result is far from being a balanced portrait of social anthropology as a whole, and certainly it would not make a suitable textbook for undergraduates (nor is it intended to be one). It also appears to insulate the book from criticism, since some comments are simply irrelevant to the author's aims; the deficiencies cited above are, he says, mostly intentional. But the personal flavour has its rewards too: the book is more stimulating, even entertaining and certainly more readable than would have been likely had the author adopted a blandly balanced approach. Leach leads us through his vision of social anthropology, offering at best some subtle and ingenious ideas about the understanding of human society and culture that will challenge the reader (particularly the non-specialist) to real thought: and he does this in his usual admirable manner — clear and trenchant in expression, and direct and conversational in tone.

Roughly the first half of the book deals with general issues, mainly different views of humanity. Leach starts by distinguishing social anthropologists from cultural anthropologists, empiricists from rational idealists, and so on. As he gives his account of these and other cross-cutting distinctions, he naturally argues for his own position — British social anthropology as a kind of micro-sociology, blending Malinowskian empiricism and Levi-Straussian rationalism in the study of the day-to-day lives of small communities, with the aim of gaining insight, in a quasi-literary sense, into human behaviour. At the same time he denounces opposing positions, with polemical shots at conjectural historical reconstruction, cross-cultural comparison of isolated "traits", natural science thinking about human society, and other anthropological practices of which he disapproves. He then discusses criteria and concepts of humanity and animality, as a philosophical and anthropological problem rather than a purely taxonomic one. This first half concludes with what is perhaps a key declaration:

> I myself view the varieties of human society as alternative systems of moral order rather than as a sequence of specialized adaptations to different economic circumstances.

In the second half, the focus shifts to a closer look at what social anthropologists actually study. In Leach's view, the three main spheres of concern to social anthropology are economy, kinship and cosmology (or, roughly, religion). These are not treated equally. Kinship, traditionally a prime concern in social anthropology and one which extends well beyond what readers in modern industrial society might associate with the term, is discussed at some length: the conceptual complexities of the subject, and its connections with indebtedness, power, alliance and so forth are illustrated. The interlocking relationships between economy, kinship and cosmology are also explored, but economy in its own right is not dealt with at all, and cosmology only in a few pages, despite Leach's particular interest in the subject. The book ends defiantly. Leach grants that social anthropology is "the study of the statics of social systems", despite the dynamic nature of all actual social systems: but recalling that in his earlier career as an engineer he found all the basic theory in the statics, he rests his case for the genuine value of social anthropology as he has presented it.

What, then, should one make of all this? I find a good deal to respect in Leach's cogent exposition, and up to a point I also find it persuasive. But I have reservations too. For one thing, I cannot deny a certain disappointment at the proportions of the book: the first half seems too long for its material and the second too short, especially on subjects such as cosmology. For another, the vehemence of Leach's rhetoric certainly makes for lively reading, but I think he overdoes it. The attacks on opponents are apt to become overbearing, and are sometimes plain wrong. An example of the latter comes when he accuses ethologists of assuming, among other things, that "emotions and attitudes are just as much observable characteristics as colours or structures" — a remarkable misrepresentation that presumably reflects a lack of consultation with ethologists such as his Cambridge colleague and fellow "master", Robert Hinde (whose *Ethology* was reviewed in *Nature* **296**, 507; 1982).

Other attacks — for example on Geertz for an "unverifiable" statement about Balinese culture and society, on a sociobiological "just-so story", and on E.O. Wilson for the "startling incompetence" of his anthropology — may perhaps have more justice in them. The briskness with which such shortcomings are dismissed conveys the impression of commendably rigorous standards: but I think one may question whether everything Leach himself says has been scrutinized equally severely, or indeed whether it would have been reasonable to do so, given the nature of the subject matter. A possibly more straightforward issue of consistency arises within Leach's own arguments. On some points, including important ones such as the place of generalizing in social anthropology, he seems to argue in different directions as the book proceeds, creating a rather equivocal overall impression despite the clarity of particular passages.

It is conspicuous that Leach's most forceful points are frequently negative ones — not only criticizing opponents, but closing off avenues of enquiry and interdisciplinary contacts that he considers worthless. This no doubt reflects a sceptical habit of mind born of long experience, and in itself it seems defensible: indeed as an antidote to fashionable concerns it can be refreshing. Nonetheless, the cumulative effect seems to risk discouraging innovation. To my surprise, physical (biological) anthropology is one instance where Leach nods respectfully in the direction of interdisciplinary dialogue: yet this seems counter to the tenor of the argument, and the point is not pursued.

Finally, at a more mundane level, Leach is at times quite cavalier when it comes to matters of definition (e.g. species) and fact (e.g. confusing irrigation and drainage in New Guinea agriculture).

Like Aubrey Manning in his review of Hinde's *Ethology*, I am uncertain about the intended audience of the *Masterguide* series. Leach's imaginary reader is

> someone like myself at the age of twenty-five to whom learning about anthropology came as an unexpected intrusion into a deceptively well-organized existence.

Social Anthropology is lively and stimulating enough to be recommended to such a reader, with the important caution that is also personal in flavour and erratic in approach. It is, for once, a book that matches its description in the cover blurb — "fascinating and idiosyncratic". ☐

Not much that's new in cancer research

Peter Alexander

Cancer: A Comprehensive Treatise, 2nd Edn. Vol. 1, *Etiology: Chemical and Physical Carcinogenesis*. Edited by Frederick F. Becker. Pp.714. ISBN 0-306-40701-9. (Plenum: 1982.) $69.50, £43.79.

RESEARCH into cancer embraces an enormous range of disciplines, yet a broad understanding of the subject as a whole is necessary if the specialist investigator is to exploit the best opportunities available and is to evaluate the implications of his findings. A comprehensive treatment of cancer research, therefore, fills a very real need.

In 1975 such a treatise appeared. Edited by Professor F.F. Becker, the six-volume work was splendidly produced and most of the chapters were both readable and authoritative. Publication delays inherent in such a mammoth undertaking meant that the literature was only covered until 1973, and this most useful source is now only of value in some restricted areas. The pace of cancer research within the past decade has been rapid in most areas and some have changed out of all recognition. At the cellular and sub-cellular level the new techniques of gene cloning, production of monoclonal antibodies and the isolation and characterization of growth factors have provided a plethora of new facts and theories which supersede much of the earlier work.

A second edition of Becker's work was, therefore, keenly awaited and a revised version of Vol. 1 has now appeared. This, unfortunately, is a great disappointment because attempts to bring it up to date have been very patchy. The second edition contains 40 per cent more pages, but this increase is largely accounted for by the introduction of three new chapters and the extensive revision of three chapters dealing with the metabolism and biochemistry of chemical carcinogens. In all, there are 19 chapters of which six are direct reprints of the first edition with no alteration or additions; they contain no references beyond 1973 and cover the role in cancer induction of genetics, hormones, immunology and radiation. There is a further set of chapters which, while not identical reproductions of the first edition, have been changed only marginally and fail to reflect adequately the advances since 1973. Approximately half the book is, therefore, useless as a guide to the current state of knowledge. As a reference source to the older literature, these chapters have some worth, but why reprint them when copies of the first edition are readily accessible in so many libraries?

Much of the remainder is made up of some quite excellent contributions, however, which are of value both to those who wish to gain a general feel of the field as a whole and to researchers directly engaged in the area reviewed. In general, they do not suffer greatly from the fact that, even in the new chapters, the literature is only covered until 1979. Notable amongst these are the chapters on cytogenetics by P.C. Nowell, epidemiology (V.F. Guinee), the metabolism (J.H. Weisburger and S.M. Williams) and interaction with nucleic acids (S. Rajalakshimi *et al.*) of carcinogens, and two articles on the two-stage mechanism of carcinogens by, respectively, I. Berenblum and E. Farber. What a pity that these articles were not published by themselves, since it is difficult to recommend the purchase of an expensive book in which virtually half of the contents are available in an earlier edition. ☐

Peter Alexander is Professor and Head of the Division of Tumour Immunology at the Institute of Cancer Research, Sutton, Surrey.

Fusion forever

R.S. Pease

Fusion. Vol.1, *Magnetic Confinement*, 2 parts. Edited by Edward Teller. Part A, pp.491, ISBN 0-12-685201-4; Part B, pp.529, ISBN 0-12-685241-3. (Academic: 1982.) Part A $56, £37; Part B $59, £39.

IN 1930, the installed electricity generating capacity of the Soviet Union was 2. GWatts. According to Professor Teller' introduction to these books, the entir supply of Leningrad — perhaps a third o the 2.9 GWatts — was offered to Georg Gamow for experiments to create th fusion-energy-producing temperature the recently suggested as the source of th limitless solar energy. The offer (write Teller) was refused. Today, over 50 year later, we can anticipate such experiments a the Joint European Torus in Europe an the Tokamak Fusion Test Reactor i America coming into operation next year they indeed use power supplies of th magnitude offered to Gamow b Bukharin. The publication of these presen volumes, the first in a new series describin the state of fusion research and the hope and uncertainties of the researchers, is thu very timely.

The first eleven chapters of the tw companion volumes comprising Vol.1 ar devoted to accounts of research on th confinement of hydrogen isotopes b magnetic fields. A further two chapte describe the methods proposed to heat th plasma to the required 100M° temperatures; and the final three chapte describe the work on technology and engineering carried out to explore the possibility of practical extraction of power from the hoped-for large-scale fusion reactions.

Each chapter is largely self-contained, and is written by a leading authority at a level which, though demanding concentration, will be rewarding for many physicists and engineers outside this field of research. At the same time, for specialists in fusion research, the articles are comprehensive, accurate, up-to-date (to about 1980) and have excellent, though not exhaustive bibliographies. Each contribution is concerned with theory and experiment in one of the main configurations of magnetic field which might form the basis of a reactor: the Tokamak, the Stellarator, the Mirror Machine, the Reverse Field Pinch and so forth. This form of presentation has the advantage that it is relatively easy to comprehend the state of play in each of these approaches, even if the reader will sometimes have to take into account what is not said as well as what is. The disadvantages are that there is some duplication of material; that the overall presentation of confinement physics is somewhat haphazard; and that important investigations of magnetic-confinement using systems, such as the Levitron, not regarded as the basis of a reactor, are omitted.

The balance of the material reflects that of the current research programme in the United States, with major articles on the theory and experiment of Tokamaks and Mirror Machines, respectively; whilst the Stellarators, though a pioneering achievement of the early US programme, are here dealt with relatively briefly. Some of the contributions bring together important material hitherto unpublished or widely scattered throughout the literature, notably the short chapter on the so-called ELMO (after St Elmo's fire) Bumpy Torus, and the chapter on Advanced Fusion Reactors. Others — those on the Tokamak system and on Magnetic Fusion Reactors — achieve a mastery over a vast literature for which both specialists and non-specialists alike will be grateful. Professor Teller's own chapter and his assembly of authors and material has ensured that there is now available for graduate engineers and physicists in general — as well as for the specialists — an up-to-date account of the main features of the physics and engineering of magnetic confinement fusion.

On the wider issue of whether or not this research will finally come to fruition, the book offers a combination of long-term confidence and short-term caution appropriate when the main ideas are subject to the imminent test of major experimentation. □

R.S. Pease is the UKAEA's Programme Director for Fusion Research, and is currently Chairman of the International Fusion Research Council.

Between the laboratory and the patient

John P. Bunker & Jinnet Fowles

Biomedical Innovation. Edited by Edward B. Roberts *et al.* Pp.395. ISBN 0-262-18103-7. (MIT Press: 1982.) $30, £17.

Most of us would agree that an ideal model for biomedical innovation, the process by which new diagnostic and therapeutic technologies are conceived, developed and disseminated would look something like this: a strong, adequately funded, basic research capability; prompt evaluation of the new procedure by well-designed clinical trials; a favourable balance of benefits and risks; a well-informed public, able to appreciate the consequences of treatment; timely application of the medical technology to the relief of human suffering; translation of the results into appropriate standards for general clinical practice; and continued monitoring or surveillance for long-term effects. The authors of *Biomedical Innovation* make it clear how far we are from achieving such perfection.

We are encouraged at the outset by Julius Comroe, who recounts the landmark studies in which he and the late Robert Dripps documented the benefits of strong basic science. Comroe and Dripps conducted a six-year study of the top ten clinical advances in cardiovascular-pulmonary medicine between 1945 and 1975 to determine whether they were mainly the result of targeted or of untargeted research. Their study was, in fact, a response to a Department of Defense study of weapon development which had concluded that scientists were most effective when their effort was mission-oriented. The Comroe–Dripps study, based on an examination of 4,000 published articles, came to the opposite conclusion: that the great advances in the treatment of cardiovascular disease were based on a strong, undirected, basic research effort. Since this process is already established, the message is a simple one: don't meddle.

Prompt evaluation, or the process of "knowledge validation", is described in fascinating detail by Robert Levy and Edward Sondik of the National Heart, Lung, and Blood Institute (NHLBI) — the multiple steps by which the Institute decides which of a possible portfolio of clinical trials should be undertaken given that these trials draw funds away from the support of knowledge acquisition.

One could almost believe that the 15 per cent of its extramural budget devoted by NHLBI to clinical trials is a sufficient investment in evaluation. Unfortunately, NHLBI appears to be the exception, for ample evidence is presented elsewhere in *Biomedical Innovation* that current efforts at clinical evaluation are inadequate. Worse, we now know that the current federal administration, as a matter of policy, intends to reduce further its investment in clinical trials in favour of support for basic research.

However unsatisfactory the record of clinical evaluation may be, the goal of a well-informed public ("informed consent") appears to be even more distant. While providing no new insights, Laurence Tancredi calls attention to four of the major unsolved conceptual problems of informed consent: the ability of the patient to comprehend the information provided by physicians; the nature of the judgements made under this uncertainty; the placebo effect; and the accuracy of available data. He concludes that these conceptual issues "create serious questions about the validity and meaningfulness of informed consent as a protective device". In his pessimistic appraisal, Tancredi slights the evidence of randomized trials demonstrating improvements in patients' understanding of the implications of treatment and even in the medical outcomes. Nonetheless, although there are indeed many obstacles to an effective informed consent process, there have been undoubted gains in the effectiveness with which information can be made available to the patient. Emphasis on the timing of information, as well as appropriate levels of vocabulary and organization, have increased patient comprehension and thoughtful decision-making.

Timely application of new medical technology is barely mentioned as an issue, which seems odd in view of the recent discussions of the so-called "drug lag" in professional journals and the lay press. Acknowledging the past existence of "considerable lag time", the editors, in an introductory chapter, state that "whether lag time exists today is essentially unanswered . . . but . . . is a concern we must continually explore". Unfortunately the reader searching for enlightenment on this thorny and controversial issue will be disappointed.

We now come to the unresolved issue which Donald Young calls "deficiencies in the communication of research results". Dr Young examines the dissemination of findings from two large clinical trials, the Veterans' Administration Cooperative Study of Surgery for Coronary Artery Disease and the NHLBI Cooperative Study of Unstable Angina Pectoris. On the basis of these two studies, he concludes that the published medical research literature is largely irrelevant to the information needs of practitioners and that there is inadequate guidance for practising physicians attempting to resolve the frequent conflicts encountered in clinical trial results. The issue he raises, the lack of evaluation of medical technology that reflects users' needs, is a theme that recurs throughout the book — which is not surprising; in comparison with basic research, and despite their undoubted worth, evaluation studies have been woefully underfunded.

The final phase of our model, continued monitoring or surveillance, may be the most neglected. Herbert Klarman, in his chapter "Measuring Economic Effects of Biomedical Innovation", declares that monitoring the effects of technology is inherently superior to forecasting as a basis for planning. He even suggests that monitoring could serve as a basis for reimbursement of physicians and hospitals, and that this might be a better way to regulate biomedical innovation than certificate-of-need, which depends on forecasting. Great Britain has, of course, already opted for earlier introduction of drugs, relying more heavily on post-marketing surveillance. In the United States, unfortunately, and despite extensive professional debate and encouragement, no comprehensive programme of post-marketing surveillance is yet in sight.

The method used by Young and by Levy and Sondik, as well as by several of the other authors in *Biomedical Innovation*, is "research on research" — the study of the research process as revealed in the medical literature. Much of their material has been published in other forms previously, and sadly the opportunity to use this collection to develop a cohesive and comprehensive thesis has been largely missed. But it is too much to expect a multi-authored book emerging from a three-day conference to read as if it were the product of a single, all-knowing intelligence. Rather, it is a valuable collection of essays that contains much useful information and many insights. It will be a convenient sourcebook for those who wish to understand the current process of biomedical innovation or who choose to write about it in the future. □

John P. Bunker and Jinnet Fowles are in the Health Services Research Program at Stanford University.

Mulliken on molecular orbitals

W. G. Richards

Polyatomic Molecules: Results of ab Initio *Calculations.* By Robert S. Mulliken and Walter C. Ermler. Pp.431. ISBN 0-12-509860-X. (Academic: 1982.) $49, £32.40.

Charles Coulson once suggested that the acronym MO should stand for Mulliken Orbitals rather than for Molecular Orbitals. Robert Mulliken was one of the originators of the method of obtaining solutions of the Schrödinger equation for molecules in a manner paralleling that used for atoms, each electron having its own individual function or orbital. How heartening, then, that the great man should still be active and at the forefront of the discipline. Not for Mulliken the contempt for computers; he seizes on the power which can produce accurate functions and a precision in computed properties which may on occasion rival that available from experiment.

Together with Walter Ermler, in this book he presents a comprehensive survey of *ab initio* calculations on polyatomic molecules. The epithet *ab initio* may sometimes give a spurious impression of quality; merely performing all the integrations implied in a Roothaan–Hartree–Fock calculation does not cover over defects in the original theory. In an introduction the authors do go beyond the minimum required by their title, discussing matters such as configuration interaction, electron pair and many-body approaches to improvement of wavefunction, as well as pseudopotentials.

Subsequent chapters each treat general classes of molecules, for example AH$_2$; AB$_2$; ABC; molecules with specified symmetry; reaction surfaces and organic compounds. In every case general considerations are followed by specific results obtained for individual molecules. Copious references mean that this is a very comprehensive survey, invaluable to theoretical chemists, to spectroscopists and to the growing band of those who describe themselves as computational chemists.

The appetite for this type of work shows no sign of abating and indeed it is being stimulated by developments in computer hardware. Cheaper and more powerful minicomputers mean that experimental chemists can run *ab initio* calculations for themselves using freely available programs obtainable from the admirable Quantum Chemistry Program Exchange run from the University of Indiana. At the same time, the new breed of supercomputer with vector and array processors offers the chance of doing extremely accurate calculations on molecules which were until recently too complex to be contemplated.

Although there is no hint of a plateau in the output of quantum mechanical calculations the book is timely in that it surveys the field, describing what has been done before the new machines have a major impact. □

W. Graham Richards is a Lecturer in the Physical Chemistry Laboratory at Oxford University. The latest volume of his Bibliography of *Ab Initio* Molecular Wavefunctions *covering 1978–1980 was published by Oxford University Press last year.*

More for less

Peter W.J. Rigby

DNA Tumor Viruses, 2nd Edn revised. Edited by John Tooze. Pp.1,073. Hbk ISBN 0-87969-142-5; pbk ISBN 0-87969-141-7. (Cold Spring Harbor Laboratory: 1981.) US hbk $75, pbk $32.50; elsewhere hbk $90, pbk $39.

This revision of the bible of DNA tumour virology is to be warmly welcomed. That reprinting should be necessary within 18 months of publication of the original edition emphasizes the value of the book, and the editor is to be congratulated on having seized this opportunity to improve the text considerably.

The basic material is unaltered but the book has been updated by adding supplements to nine of the thirteen chapters. These supplements vary considerably in length and comprehensiveness, but they do describe the recent major advances in the field. The additional material deals effectively with such topics as polyoma middle T-antigen, the p53 protein associated with large T-antigen in SV40-transformed cells and the molecular biology of BKV, thus obviating criticisms expressed in my review of the original book (*Nature* **289**, 332; 1981). The appendices of DNA sequence data have been considerably enlarged. The SV40 sequence has been modified to take account of the extra nucleotides, and another welcome addition to this section is a tabulation of restriction fragments. The sections on human adenoviruses contain a large amount of fresh sequence data and there are new appendices dealing with simian and murine adenoviruses and adenovirus–SV40 hybrids.

The book now contains some 1,100 pages which, at a price of less than $40 for the paperback edition, represents extraordinary value. The appearance of a paperback version is the most pleasing aspect of the revision as the book is now within the economic reach of the many advanced undergraduate and graduate students who ought to own a copy. This excellent volume will be, for many years to come, compulsory reading for everyone with an interest in any aspect of DNA tumour virology. □

Peter W.J. Rigby is a member of the Cancer Research Campaign Eukaryotic Molecular Genetics Research Group and a Senior Lecturer in Biochemistry at Imperial College, University of London.

● The National Physical Laboratory has recently issued a second edition of their information poster, *Units of Measurement.* The chart summarizes the SI system and illustrates how the units are realized at the NPL. It may be obtained by writing to Information Services, NPL, Teddington Middlesex TW11 0LW, enclosing a stamped addressed C4 envelope.

5 August 1982

James Watt and biotechnology

The British government is being deluged by advice about the proper exploitation of biotechnology, which is in itself a symptom of what is wrong. The government should think of cutting loose.

Just over two hundred years ago, when James Watt had developed his crucial improvement of Newcomen's steam engine, it seems not to have entered the heads of the British Parliament or of the Prime Minister of the day (the Marquis of Rockingham in the second half of 1765) to set up a committee to recommend how this important innovation could best be exploited. But, in the event, for the best part of the succeeding century, Britain profited enormously from James Watt's doings. So what is so different nowadays? That is what the present British government should ask itself before setting out to reply to the latest contribution to the stream of unsolicited advice it has been given in the past few years about the exploitation of biotechnology. Two years ago, a committee under the late Sir Alfred Spinks tried to persuade the government that it had an important role to play. A year later, the government issued a defensive and temporizing reply. Now, the Education, Science and Arts Committee of the House of Commons has predictably (see page 507) complained that the government has done too little about Spinks, and makes a string of suggestions of its own, some sensible and some not. The form now would be for the government to produce another defensive reply and for some other committee to protest that the reply is unsatisfactory. And so the cycle would continue. Because the process would do nothing (except perhaps harm) for biotechnology, the government should now bend its energies to asking how far it is prepared to go to create a climate in which innovation can flourish again.

Communication

To go back to James Watt would do no harm, as a consideration of the advice the government was offered last week will readily show. Thus the House of Commons asks that there should be a "formal channel of communication" between the Department of Industry (a huge department of state) and the University Grants Committee (a tiny and constitutionally ambiguous entity responsible for saying how what the government decides should be spent on universities should be divided among them) so that the former can tell the latter what it has already told the committee (and in public) — that it would like to see more of the universities' resources spent on science and technology. Can that channel of communication really be necessary? Simple-minded people might think that Mr Patrick Jenkin, the industry man, might simply write to Sir Keith Joseph, the education man (who also happens to be his predecessor), asking him to use his influence with the grants committee, to which he has in any case recently taken to writing open letters (see *Nature* 22 July, p.313). Or perhaps the two ministers might exchange a few civil words after some convenient meeting of the Cabinet to which they both belong? "What about a trenchant postscript, Keith, to your next letter to those . . . people?", Patrick might ask. By now, both participants know too well that such strategems will have no effect. For neither of them can speak freely to the other until what he thinks he might say has been solemnly considered by his own civil servants and then, perhaps, by an interdepartmental committee (which takes even longer to arrange). And the House of Commons committee, constitutionally the only defence against the executive, finds itself lending its name to a proposal that civil servants from yet another ministry should have a right to attend meetings of the grants committee. Is that how steam engines might have been exploited?

Of course not. The Marquis of Rockingham knew that by instinct. Why is the present British government, whose political inclinations are not very different, by comparison so diffident and unsure? Watt's steam engines made their way in the eighteenth century, and then made the nineteenth century for Britain, because there was an army of British manufacturers who fought their way to Watt's door (and later to that of Boulton and Watt) to place an order and to risk the money that went with it in the hope of being able to keep ahead (make a better profit or win a larger share of the market) of their competitors. To be sure, economic circumstances were different while direct taxes were negligible, so that capital expenditure (on, say, a steam engine) was a direct replacement for current expenditure and not, as it is at present, partly the purchase of a capital asset. The mechanisms of trade were also primitive, so that competition was less ferocious and, as a consequence, profit margins higher. But there were also people who thought the game worth the candle, who were prepared to take a risk — the risk that they might be wrong. What has happened to them? And if they have disappeared for good, what is being done to recreate them? So far, it seems, not very much.

Yet it is also plain the British government, three years after its election, is at a turning-point in its industrial affairs. Originally, the promise was that reducing income tax would create what were called incentives, persuading people to spend their tax rebates on industrial investment. That stratagem seems not to have worked as planned. But the government at the outset planned to pull back from the direct management of industry, selling off bits and pieces of previously nationalized industries wherever it could, on the grounds that governments are inherently bad managers but also because it had become impossible to finance the annual capital investment of major industries together with the increased social costs that modern states must pay out. The past few weeks have been a great disappointment. The state communications monopoly, British Telecom, is to be sold but not until after the next election. British Aerospace (which works primarily for the government) may have half-gone, but British Airways is destined to make such a huge loss in the present financial year that is unlikely to be saleable next year at more than the scrap value of its equipment. The hope that British Steel will be saleable has faded as the prospect has increased that its next reported loss will be getting on for two per cent of the GNP. Yet the Confederation of British Industry and the major clearing banks are at their wits' ends to know what should be done to keep quite substantial companies in business, while unemployment is well above three million. Who, in these circumstances, will suppose that the future for the British economy lies in the creation of a channel of communication between the Department of Industry and the University Grants Committee?

De-industrialization

The truth is that the de-industrialization of Britain is already well-advanced. After a decade of gloomy speculation on that theme, the prospect is now within sight of becoming a reality. The present government, a victim of circumstance its historians may claim, has to choose between the stark alternatives that lie ahead — gracefully to let the process continue (but nevertheless fighting for the channel of communication between the Department of

0028-0836/82/310501 02$01.00

Industry and the University Grants Committee) and recreating the circumstances that enabled Mr Watt to prosper. Even though the torrent of advice that the government is now given about the exploitation of biotechnology is largely empty of constructive content (because it supposes that all innovations will be conducted within the framework to which all have grown accustomed), the fact that there is so much of it must surely be a sign that something needs to be decided.

The case of biotechnology is marvellously illustrative of what lies ahead. Popular legend has it that laboratory discoveries in the immediate past could be made the foundation of a brave new industry, one so productive and profitable that, with a little luck, some entrepreneurial government might succeed as James Watt did. Modern biotechnology will indeed change the world in welcome ways, but not necessarily more profoundly than it has done so already. (Where would we be without bread, or cheese, or wine?) Equally, however, it is certain that in the long run the benefits will accrue to those commercial organizations that are so technically and financially strong, or so imaginative and fiscally free, that they can make the best bargains with their present customers and an uncertain future. Inevitably, of course, in the intervening years or decades, many small enterprises will spring into being (and some may even prosper in the long term), but those responsible for founding them will only rarely make their marks by becoming household words, names on some pharmaceutical package or other new commodity. Most will be content to sell out to larger partners, and some will be glad to do so. Those doubting that calculation should consider what happened to the manufacturers of automobiles who set out a century ago on their endeavour. The difference, now, is that the market, both for products and people, is international. The House of Commons committee at least knows that.

So why should not Britain follow in biotechnology where the government of France appears to be going in its attempt to make a new electronics industry (see page 507)? Because the British have been through that, most recently in the 1960s. Many of the projects mounted then in the belief that profligate public investment in new technology must be virtuous are only now being painfully abandoned — the aluminium smelter in the north of Scotland, for example. What has stuck in the British mind is merely that this is a recipe for an inflation rate that is insupportable. If the French avoid that painful trauma, it will be because their civil servants are more businessmen than bureaucrats.

The British government's concern, in the face of the conflicting advice being showered on it, must be to give British industry a sporting chance of survival. How should that be done? Most committees with an opinion on the subject say that British universities are even in penury remarkably productive of good fundamental research, but the research councils' own committee of officials acknowledges that the peer-review system may inhibit applied research in universities (see page 507). That is not, of course, a contradiction but a simple consequence. Who is to change it, and how? Certainly there is no room for change within the present system, although there might be if universities were genuinely autonomous and not as at present constrained by an invidious *numerus clausus* applied to their total size. The time has probably come when the British system for research support must follow the course being followed by universities in the United States, looking for closer links betwen universities and industry (with all the discomfort that must follow), in which case tax concessions are necessary — not merely matters to be studied. And while the research councils themselves are probably quite able managers of their own research and development, there is very little to be said for allowing them to continue as they are while the work they do might as well be done in the more flexible (and perhaps cheaper) environment of the universities. The House of Commons committee is right to say that change is overdue, but it underestimates the degree to which the necessary change must be radical. A formal channel of communication between the Department of Industry and the University Grants Committee is not a sufficient substitute.

Talk, guns and butter

President Reagan is more flexible about India than his predecessor, but still has much to learn.

President Reagan's diplomacy is better than that of his predecessor, Jimmy Carter, at least where relations with India are concerned. By working out an ingenious way round the impasse over the supply of nuclear fuel to India (see p.503), Reagan has extricated US diplomacy from the trap created by Carter, who campaigned against nuclear proliferation, supported the 1978 anti-proliferation act but then had to bend to Indian pressure and send nuclear fuels to a state that has consistently refused to forswear the development of nuclear weapons. The relief that greeted the Tarapur deal last week in Washington indicated that a thaw in US–Indian relations is overdue. But a thaw does not solve the problems of that part of the world nor signal a clear path for future US diplomacy. Indeed, the Tarapur deal may be a little too cynical. After all, why should the United States, with its long record of efforts to prevent proliferation, bow to a nation that was the chief opponent of the Nuclear Non-Proliferation Treaty, and which mightily inflamed the nuclear ambitions of other developing countries with its "peaceful" nuclear test in 1974?

Why should Mrs Gandhi, who otherwise seemed to be bearing olive branches to Washington last week, keep the nuclear weapons option open? "We do not have nuclear weapons", she told a gathering at the National Press Club, sounding faintly like those Israeli generals who always deny that Israel has "deliverable" nuclear bombs. Most people, especially the Pakistanis who seem to be bent on a nuclear weapons capability of thier own, assume that India could use a nuclear weapon if it so chose. Is it not, after all, an emblem of India's advanced science and technology? India says the reason for keeping the nuclear weapons option open is Pakistan, and has been highly critical of the new $3,200 million dollar arms package the Reagan Administration has put together for India's worst enemy. Ever since the Soviet invasion of Afghanistan in 1980, Washington has tried to treat the Pakistani government as some kind of Western bulwark. Yet the military aid, as usual, seems not to be going to fortify Pakistan defences along the Afghan border as intended. According to Mrs Gandhi, the arms keep massing on the Indian border, and attempts to sign a "no-war pact" seem always to end in failure.

This is one reason why Mrs Gandhi was in Washington last week: to rectify the long-standing impression that India "tilts" to the Soviet Union, and thus is forcing Washington to "tilt" to Pakistan. Asked point-blank which way India is tilting these days, Mrs Gandhi told a reporter "We stand upright" — and her American audience applauded. She also hinted that it might be possible for the Soviets to leave Afghanistan under some kind of negotiated agreement — a development that would also remove Washington's need to support Pakistan. But such global machinations could hardly be carried out in a single state visit. "Our main purpose is to put across the Indian point of view" she explained. She appeared to imply that she would be returning to Washington.

Mrs Gandhi also had a more specific purpose: to persuade the President that India needs substantial low-cost loans from other governments and international lending institutions if it is to become the kind of free-enterprise state the President would admire. On this point, however, she did not succeed. Although she stressed India's progressive Western-oriented view of development — hence India's interest in bilateral science cooperation with the United States — she failed to turn that impression into money. Apparently the President insisted that there could be no increase of the US contribution to the International Development Association (which mainly lends to India) and urged her to borrow in the commercial markets. So President Reagan has extended a handshake even while denying India a scrap of extra money to aid Indian development, science and technology. It is politic for the President to be that tough, but is it wise?

Gandhi puts India's claim to USA

New science link agreed but no money

Washington

Indian Prime Minister Mrs Indira Gandhi made her first visit to Washington in 11 years last week, during which she and President Ronald Reagan announced not only a settlement of the long-standing dispute over nuclear fuels for the Indian nuclear reactors at Tarapur but also a new high-level agreement on cooperation in science and technology.

Like the agreements on science that Washington signed with Moscow and later with Peking in the early 1970s as a prelude to improved relations, the science accord could signal a new period of stable relations between Washington and New Delhi, which have been troubled for some years (see opposite).

In a day and a half of meetings with the President, members of Congress, the press and scientists, Mrs Gandhi made it clear that India does not consider itself a supplicant for US aid monies or hand-me-down technology from the United States. In a talk to the American Association for the Advancement of Science, she stressed India's strong indigenous high-science traditions, which have included world-class contributions in many basic fields.

"It is an inherent obligation of a great country such as India, with its traditions of scholarship and original thinking and its great cultural heritage, to participate fully in the march of science", said Mrs Gandhi, quoting from the latest resolution on national science policy.

On the other hand, India most needs science and technology to serve development down to the village level as with the "fitting of tyres on bullock carts and the use of biogas plants", she said.

The new accord establishes a committee to be chaired jointly by Dr George A. Keyworth, the President's science adviser, and Professor M.G.K. Menon, chairman of the Indian Science Advisory Council. Other members have still to be chosen. The committee should produce suggestions for collaborative work by early next year, according to the White House, But the new group, while enjoying prestige, has not had any money allocated to it and it is not clear how any programmes it suggests will be carried out or funded.

Nyle C. Brady, senior assistant administrator of the US Agency for International Development, who will help to select the members of the committee, says that some projects could be funded by reshuffling the existing $80 million in foreign aid that his agency gives to India each year. He estimated that 10–20 per cent of the money now goes on projects based on science and technology items. (Mrs Gandhi also tried to persuade the President of the importance of concessional financing to India for general development, but her arguments are said to have fallen on deaf ears.)

Likely areas of collaboration suggested by Mrs Gandhi and US officials include:

- Biomedical research to control leprosy, tuberculosis and waterborne diseases. India claims recently to have made advances in the control of leprosy, while US investigators are the source of its only natural host for experimental infection, the nine-banded armadillo.
- Nutritional blindness associated with severe vitamin A deficiency, a leading cause of blindness in many developing nations. Related work is already under way in the United States, and US–Indian collaboration is taking place at the National Institute of Nutrition in Hyderabad.
- Birth control, especially development of possible vaccines as anti-fertility measures.
- Agriculture and biomass. India has achieved self-sufficiency in grain production, a remarkable achievement for a nation of 700 million people. But, as Mrs Gandhi told reporters in Washington, most modern grain production increases consumption of energy. Energy conservation and cheap energy production are important priorities for the achivement of future increases in food production and overall standards of nutrition. The US Department of Agriculture and the land-grant colleges already contribute to this work.

India is especially interested in the possi-

France to supply Tarapur fuels

Washington

A major problem in US–Indian relations was removed last week when President Ronald Reagan and Prime Minister Indira Gandhi announced that they had resolved a long-standing dispute over whether the United States should continue to provide low-enriched uranium to Indian reactors at Tarapur, outside Bombay.

The two heads of state announced that the reactors would be able to keep operating because fuel would be provided by a third party, France. This circumvents a 1978 US law that appears to supersede the 1963 agreement and effectively bars US shipments to Tarapur. In return, India will continue to observe safeguards operated by the International Atomic Energy Agency.

Under the 1963 agreement, the United States became the exclusive supplier of low-enriched uranium to Tarapur. In return, India promised to observe bilateral safeguards.

But in 1978, Congress passed the nuclear anti-proliferation act which prohibited US export of nuclear fuels to any country that had not signed the 1968 Non-Proliferation Treaty. India has deliberately remained outside the treaty, so the act seemed to prevent continued shipments to Tarapur.

Under pressure from the Indian government, President Carter in 1980 used a provision in the 1978 act to authorize shipment of 38 tonnes of enriched uranium to Tarapur anyway. As recently as April 1981, the Reagan Administration was reported to be ready to cancel the 1963 agreement, and India was reported to be threatening to stop observing safeguards at Tarapur.

Under the new agreement, however, both the 1963 agreement and the 1978 act are upheld. The United States will not supply fuel to Tarapur — instead, the French will do so. But there are some sticking points, such as India's continued insistence that, under the 1963 agreement, it does not need US permission to reprocess spent fuel from Tarapur. It is estimated that there are 200 tonnes of fuel at Tarapur, 100 tonnes in the form of spent fuel and another 100 tonnes in the reactors. If all this were reprocessed into weapons grade material, it could be enough for 100 nuclear devices.

Two congressional watchdogs of nuclear proliferation, Representative Jonathan Bingham (Democrat, New York) and Senator John Glenn (Democrat, Ohio), say they are content with the Reagan–Gandhi deal. **Deborah Shapley**

France's decision

In France, the decision to supply the enriched uranium has been taken at the political level; commercial questions such as price have yet to be decided.

Moreover, some political problems may still remain. For the enriched fuel would be produced by the Eurodif plant at Tricastin in the Rhône valley and Eurodif is not French but an international consortium of France, Italy, Spain, Belgium and Iran. Through a surviving Franco-Iranian company, Sofidif, Iran still owns 10 per cent of in Eurodif.

In principle Cogema, the French nuclear fuel company which owns 51 per cent of Eurodif, could buy the enriched uranium from Eurodif and resell it to India; or Eurodif itself could make the deal. Both arrangements might be expected to require the agreement of the other Eurodif partners. No decision on either arrangement has yet been taken, say French sources. **Robert Walgate**

Wide-World Photo

Secretary of State George Schultz follows Mrs Gandhi's lead.

bilities of genetic engineering for the improvement of crop yields and to produce quick-growing trees to provide fodder and firewood for rural populations. Biotechnology, some Indians say, is an area where high science and the needs of development meet. Last January, Mrs Gandhi announced the creation of a National Biotechnology Board, of which Dr M.S. Swaminathan will be chairman.

- Energy, minerals and materials. Indians are already being trained in the use of the Landsat satellite for mineral surveys, and collaboration exists in the field of earthquake engineering.

The White House explained that the new committee should overcome some of the problems afflicting the subcommission on science and technology formed under the Joint Commission on Economic, Commercial, Scientific, Technological, Educational and Cultural Cooperation. The commission was created in 1974 in an earlier effort at US–Indian detente, in spite of US unhappiness with India's nuclear test a few months earlier.

The science subcommission apparently did not include sufficiently high-ranking people and so was not influential enough with each country's bureaucracy to get major projects started. The new committee, under the joint chairmanship of Dr Keyworth and Dr Menon, should not have such difficulties.

In an oblique reference to the many meetings of developing countries, including one held in India last March, Mrs Gandhi noted that bilateral arrangements were the most effective path for development. "Global conferences end with inspiring and laudable statements. But their commitments are seldom honoured" she said.

Deborah Shapley

Electronics industries

French on march

The French government last week declared war on world electronics* markets with a FF140,000 million ($20,000 million) three to five-year investment programme in the French electronics industry. After nuclear power (France now has the largest and fastest-growing nuclear programme in the world) and space (where the Ariane launcher is now competing effectively with the space shuttle) comes electronics, now clearly marked out as *the* technological programme of the new socialist France.

The battle will begin in the United States. M. Abel Farnoux, principal architect of the French programme, is expected to move to an office in New York in September and one of his partners, M. Girard Compain, is to set up shop in California. Altogether, some ten French electronics policy-makers are to move to the United States this year.

Their objective will be, in part, to learn, but the real French goal is the American market. France would seek both to establish French companies in the United States and to set up cooperation agreements. But so far the French government has given no details of Farnoux's new role. The decision last week was to adopt the main lines of Farnoux's recent report on the industry (see *Nature* 27 May p.257) and to announce an investment figure.

The most difficult domestic question has been avoided — how to reorganize the French electronics industry at home. The problem is that some of the major companies — such as Thomson CSF, which produces military equipment, telephone exchanges, minicomputers, microchips, television sets and hi-fi equipment — have clear ideas of their own about their competence and company strategies, and have resented the government interference implied by their recent nationalization.

Thus Thomson was recently attempting to put its own foot in the American market through cooperation in the minicomputer market with an American company, but the French government stepped in and — despite Farnoux's attachment to the United States — insisted that Thomson link up instead with the mostly French computer company CII-Honeywell-Bull. This has riled the Thomson management, not least because the French company had earlier undermined Thomson's own minicomputer operation with the introduction of a Honeywell system (the "Level 6") despite an agreement not to do so.

Thus internal strife may make the French electronics adventure less of a threat than it might otherwise be. Meanwhile, money will certainly pour into the industry, and that alone may give it a competitive edge. It seems likely that the government will provide FF10,000 million in support of component manufacture (basically chips); FF7,000 million in consumer electronics; FF15,000 million in computers and office automation; FF15,000 million in the space industries; FF3,200 million in industrial automation; FF2,000 million in scientific instrument manufacture; FF3,000 million in medical electronics; and FF4,500 million in software production. On top of this, the industry itself is expected to invest some FF90,000 million over the planning period (to 1986), a rate not far from its present figure.

Robert Walgate

---

*The word "electronics" is used to include everything from materials production to television sets, communications and computers. The French see their 10 main competitors in the industry to be: AT&T, IBM, General Electric, ITT, Philips, Siemens, Matshushita, Hitachi, GTE and Toshiba.

Balancing the francs

The French Ministry of Research and Industry is doing its best to juggle with a tight budget for 1983 — and to make it seem not too different from the 4-year averages recently advertised in the research law passed by the National Assembly (17.8 per cent a year in real money, and 4.5 per cent a year in jobs). The budget will not be announced before September: it seems likely that the cash target will be achieved, but not the jobs.

This represents a political decision that in the short run it is more important to get on with research, and to re-equip laboratories, than to create new posts. The figures under discussion would give something like a 2–3 per cent increase in posts (up to 600 new positions) at the Centre National de la Recherche Scientifique, which is responsible for the bulk of basic science in France; 6 per cent (230 posts) at INSERM, which pursues medical research; and 3 per cent (200) at INRA (agriculture). The total civil research budget would rise the full 17.8 per cent to around FF32,000 million (£2,700 million).

All this takes place against a total government budget constrained to grow only 4.1 per cent in real terms next year, and a number of items written into the 1983 science budget that were not envisaged in the law, including FF1,000 million to help equip the science museum at La Villette, north of Paris, and FF500 million to support the computer firm CII-Honeywell-Bull.

Even so, the government is assuming only an 8 per cent inflation rate next year. Current inflation is in double figures. And in spite of the apparently large increases announced for 1982, the real increases in laboratory budgets have been eaten into by inflation and the weakness of the franc against the dollar. For example, despite a nominal 30 per cent increase, the budget of one director of a molecular biology laboratory in France this year was only 5 per cent up in buying power. But he was not complaining: "That's probably much better than my foreign colleagues".

Robert Walgate

British biotechnology

Commons ask for action

The agreement that gives the British biotechnology company Celltech exclusive rights to research carried out by the Medical Research Council was condemned last week by the Education, Science and Arts Committee of the House of Commons. In an interim report on its continuing inquiry into British biotechnology, the committee said that it is opposed to exclusivity in patent rights arising from research council work, and urged that the government should review the issue before the Agricultural Research Council comes to a similar arrangement (see *Nature* 29 July, p.412).

The committee seems to have been influenced towards this conclusion by the arguments of one witness that Celltech, having been put in a "monopoly position", must be assumed to have "responsibilities commensurate with its privileged position". The fear seems to be that some good ideas might not be pursued effectively in these circumstances.

Consistently, the committee also advocates that the British Technology Group should be deprived of its monopoly right to the first refusal of patent rights developed in research council laboratories. This goes back to 1947, when the National Research Development Corporation (now merged in the British Technology Group) was given the right to exploit (if it chose) patent rights arising from publicly supported research.

On this point, the committee seems to be pushing at an open door: the Secretary of State for Industry, Mr Patrick Jenkin, told the committee that a consideration of this question was "long overdue". For the rest (and apart from a proposal that British universities should publish lists of their members of staff holding consultancy agreements with industry), the interim report is a complaint that the British government has responded too hesitantly to the advice it has been given in the past two years followed by a string of detailed recommendations for improving the machinery of government.

Thus, the committee says, the Department of Industry should have a formal channel of communication with the University Grants Committee (UGC) so as to be able to make its opinion felt that a greater share of the universities' budget should be spent on science and technology. UGC should conversely be represented on the department's biotechnology committee (which might raise constitutional difficulties) and should set up a "more specific decision-making structure" for "strategic decisions about biotechnology".

The essence of the committee's interim report is centralist — it pleads for a "more coherent science policy" and in particular for the restoration of support for research "within the dual support system". But the report also asks that there should be a study of tax incentives as a means of stimulating industrial links with the universities and more deliberate study by the British research councils of the earmarking of student training places for intending biotechnologists.

Entrepreneurship

Monsanto act

A new venture capital fund with ambitions in biotechnology has been set up in Britain on the initiative of Monsanto, the US chemical manufacturer. Other partners in the venture include the Universities of Oxford, Cambridge and St Andrews, Imperial College London and the Nuffield Foundation, to whom the project is primarily another kind of financial investment.

The new fund will have an initial capital of £10 million (of which Monsanto will be contributing a half). The fund will be called Advent Eurofund, and will be managed by a board whose chairman is Sir Kenneth Cork,a skilled accountant.

The prospectus of the new fund is wide, covering most fields of high technology — robotics as well as biotechnology. The immediate objective is to seek minority holdings in new and established companies, investing sums between £100,000 and five times as much in order to acquire them.

Advice on prospective investments will be provided by an advisory committee including Sir Peter Hirsch and Dr W. Graham Richards (both of the University of Oxford) and Sir Hans Kornberg (University of Cambridge). Dr G. Edward Paget, director of biomedical programmes at Monsanto, will also be a member.

One member of the advisory committee said this week that his chief interest was to find ways of helping academics in British universities and elsewhere to turn their bright ideas into commercial realities. In the past few months, the venture capital scene has unexpectedly come to life in Britain. The merchant bank N.M. Rothschild has a $50 million fund for investment in biotechnology (mostly overseas), while Technical Development Capital, a subsdiary of Finance for Industry (owned by the British clearing banks) has also been active in the field. In microelectronics, there has been ill-informed controversy about the activities of Mr Jack Melchor, the Californian entrepreneur, who has apparently been testing the nerves of potential British businessmen by using £2 million from the British Technology Group to back people with ideas only if they relinquish financial control.

Signs of hope

Biotechnology is alive and well and living in at least 22 British universities. This is the burden of the first report of a body of officials called the Inter-Research Council Coordinating Committee on Biotechnology, published before the House of Commons report. In effect, it is the research councils' reply to the report prepared two years ago by a group under the late Sir Alfred Spinks meeting under the auspices of the Advisory Board for the Research Councils, the Advisory Council on Applied Research and Development and the Royal Society.

The new document, emolliently out of tune with that of the House of Commons committee, says that even before the recommendation two years ago that research council spending on biotechnology should be at least £3 million a year, expenditure amounted to £4 million in 1979-80 (and was more than £7 million the following year).

The group says, however, that it cannot accept the suggestion that successful research grant applications should include some in which there is evidence of industrial interest, but reaffirms the commitment of the research councils to "support the best science".

The research council group also resists the proposal that a small number of the centres of excellence should be established in biotechnology on the grounds of "a lack of support from government", the breadth of biotechnology and the wide distribution of relevant studies in 22 British universities.

The group says that British institutions must reconcile themselves to the loss of a proportion of people trained in Britain to posts overseas, pours cold (or at least lukewarm) water on the European programme in biotechnology and raises two subversive questions for future decision. Should British scientists who have commercial links with companies overseas be denied research council grants to support "underpinning research"? And what should be done to equalize the rewards from commercial collaboration of full-time members of research council laboratories and their intellectual partners, who "stand to gain financially to a substantially greater degree"?

One of the Spinks recommendations is, however, accepted — the need for new mechanisms to bridge what is called the "predevelopment gap" between the bench and the manufacturing plant. The document acknowledges that under peer-review, proposals designed to produce useful products "may be regarded as scientifically interesting".

0028-0836/82/310505-02$01.00

US employment

Argonne's new ways with people

Washington

Argonne National Laboratory has repeatedly evaded limits on the numbers of staff employed by referring applicants to intermediary companies known as "body shops", which supplied Argonne with "resident consultants" in exchange for overhead payments as high as 184 per cent.

This practice was one of several management irregularities at Department of Energy (DoE) laboratories revealed last week by the Senate's permanent subcommittee on investigations. The laboratories, which are largely exempt from the normal federal contract procedures, have been the subject of a year-long investigation by the subcommittee and Congress's General Accounting Office (GAO).

The use of the "body shops" appears to be the most serious abuse unearthed by the subcommittee. In one typical case, an applicant was told that she could not be employed by Argonne because of a freeze on engaging new staff but that she would instead be offered a job by an intermediary company. Her salary was $10.34 per hour; the company was paid $25.54 per hour for her services. After working as a "residential consultant" at Argonne for a year, she was taken on by the laboratory directly. She continued to do exactly the same work, and received slightly less than the $10.34 per hour she had been making as a resident consultant.

GAO found that one division at Argonne had spent $7.2 million for resident consultants since 1977, of which overhead charges by the "body shops" accounted for $4 million.

The practice of hiring professional employees through intermediaries was also popular in Argonne's Washington office. In questioning GAO Comptroller General Charles Bowsher at the subcommittee hearings last week, Senator William Roth (Republican, Delaware) brought out the fact that the Washington office had hired a nuclear engineer through Kelly Girl, a temporary office-help agency. A similar arrangement was made through the Washington School for Secretaries, which runs a temporary service. A subcommittee staff member said that "five or six" professionals had been hired this way; according to GAO, Argonne could have saved $45,000 by hiring these employees directly and avoiding the agencies' commissions of up to 50 per cent.

Argonne appears to have used the body shops not only to avoid hiring limits but also to circumvent its own education requirements. Senate investigators found several resident consultants who did not meet the laboratory's graduate-degree requirements but who had been referred to body shops by the laboratory and hired by them, usually to continue work at Argonne that they had begun as undergraduates in Argonne's student programme.

The acting under-secretary of DoE, Jan Mares, offered a mild defence of the use of body shops before the subcommittee: "managers of these laboratories need the flexibility to hire temporary people", he said, especially in the face of annual budget uncertainties and fluctuations.

Argonne's official response to the GAO study points out that the resident consultants were needed particularly at a time when Argonne was being asked to shift quickly from a concentration on nuclear energy to a much broader coverage of energy research and development. Argonne says there are now fewer than 15 resident consultants — in 1980 there were 200.

The need for flexibility was also the issue in another area, the awarding of contracts without competitive bidding. The national laboratories are allowed considerable leeway here — with the result, as GAO reported earlier this year, that for example 72 per cent of Argonne's contracts were let without bidding. At Oak Ridge National Laboratory, GAO found several instances in which the company selected by the laboratory was informed of the laboratory's budget for the project. The company's proposed costs for the project tended to show a remarkable agreement with the amount budgeted.

The laboratories' exemption from the usual federal and DoE contracting procedures led to other abuses. DoE headquarters discovered that by going through the laboratories, it could avoid those regulations in awarding its own contracts. A contract official at Brookhaven National Laboratory, for instance, was directed by DoE to award $15,000 to a particular film-maker for production of an informational film unrelated to any work then going on at Brookhaven. The project collapsed six months later when the film-maker proved "incapable of performance", according to the Senate subcommittee staff. It also turned out, said the staff, that the film-maker's "only unique qualifications were that he was in the film business and has attended graduate school with a lab employee whose office was involved in the project".

The Senate investigators said that under these "directed procurements", the laboratory officials nominally in charge of awarding contracts and overseeing performance were in fact used simply as conduits for DoE, and often did not even see any of the work.

DoE last autumn issued an order for this practice to stop. But it is still permitted when the contract is directly related to the laboratory's technical mission. DoE officials told the Senate investigators that the procedure was sometimes necessary in order to cut through the red tape of the standard procurement channels.

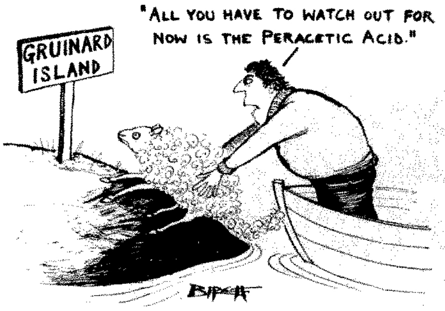
Senator Roth emphasized that he appreciated the special mission of the laboratories and their need for flexibility. But he said there is "no assurance that money is well spent" without better safeguards. And he seemed less than satisfied by DoE assurances that the problem of directed procurements had been solved by last year's order. "The oldest game in town is to issue some instruction to satisfy some senator", he said. **Stephen Budiansky**

Anthrax island

Why worry?

How do you get rid of anthrax? The announcement last week in the House of Commons that the British Ministry of Defence intends to try and clean up Gruinard Island has left several people puzzled. The island, off the north-west coast of Scotland, is contaminated with *Bacillus anthracis* spores scattered during biological warfare tests carried out during the Second World War. The ministry will use laboratory-tested chemicals in the field trial which will begin next month. What these chemicals are and why such an operation is now called for are not at all clear.

Gruinard Island is in a popular tourist area, but has been out of bounds to man and animals for nearly 40 years. Scientists from the Chemical Defence Establishment at Porton Down have been testing soil samples and trying to find an effective decontaminant for many years. A survey in 1979 showed that viable spores of *Bacillus anthracis* lay in the top 6 cm of soil and were mainly concentrated in a small area in the southern end of the island.



"ALL YOU HAVE TO WATCH OUT FOR NOW IS THE PERACETIC ACID."
GRUINARD ISLAND

The Ministry of Defence revealed its intention to carry out field trials in response to a question in the Commons by Mr Donald Stewart, MP for the Western Isles, who asked how much longer the island would be ruled unsafe for men and animals. The ministry plans to put a small party from the Chemical Defence Establishment onto the island to test the effectiveness of certain chemicals in destroying the anthrax spores. The ministry will not give any details of the chemicals in question. A representative of the Scottish Home and Health Department will accompany the scientists.

In spite of warning notices, tourists frequently stray onto Gruinard Island. In a recent incident a German and a Belgian on

0028-0836/82/310506-02$01.00

a fishing trip were apparently unable to understand the hazard warnings and wandered onto the island. *Bacillus anthracis* is particularly dangerous to humans when inhaled into the lungs — a low risk on Gruinard because the spores are buried in the soil. It can also enter the body through the gut or through cuts on the skin, when it causes spreading sores.

Officially *Bacillus anthracis* is described as a hypervirulent micro-organism which is difficult to destroy. In laboratory conditions it is susceptible to heat. Peracetic acid can also destroy anthrax spores but the acid must itself be carefully handled.

One knowledgeable person confessed himself perplexed as to why the Ministry of Defence is making such a fuss about the island. The strain of anthrax on Gruinard is not as virulent as some field strains and infection is easily treated with antibiotics. Animals can be vaccinated against the disease and in many areas, where the climate is less favourable, anthrax has been successfully eradicated through animal vaccination programmes. Gruinard Island, he said, poses no serious threat to humans. In the past anthrax has been found in animal bonemeal feed and its presence ignored. **Jane Wynn**

UK research councils

Sharing of spoils

One of the long-standing sources of jealousy among British scientists is likely to be stirred up by the decision announced last week to mount an inquiry into the ways in which research councils distribute their resources between in-house research and support for universities. The Advisory Board for the Research Councils has set up a committee under Mr J.R.S. Morris, chairman of the British subsidiary of the oil-drilling company Brown and Root, to make recommendations on the subject early in 1983.

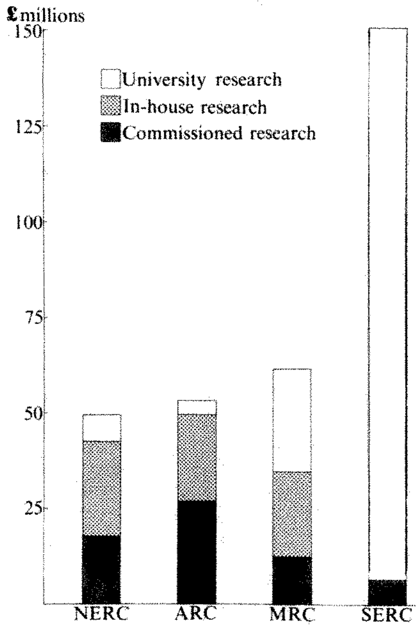
The committee is a swift response to one of the more contentious recommendations of the Merrison report on university research, published last month (see *Nature* 10 June, p.445). The report said that when research councils are under pressure, "university support may be the only or chief area" in which they can economize. In a judicious but ominous phrase, the report went on to say "we are not satisfied" that the balance between in-house spending and university support "is always right".

The committee also pointed out that during the 1970s, when government support for the research councils increased by 8 per cent in real terms, the councils' collective support for university research increased by only 3 per cent. This comparison may, however, be misleading because of the importance of salary and equipment costs in in-house budgets and research grants respectively.

Even so, some research council employees see the setting up of the new committee as an attempt by the academic scientists who account for the majority of members of the advisory board to increase the funds available for university research. Others ruefully recall that in the 1960s, the Agricultural Research Council, relatively and absolutely the most modest supporter of university research, was, on account of its dependence on in-house research, the target of the complaints that led to the Rothschild reorganization of civil science.

In practice, the new committee will have to solve several awkward problems, not least that of deciding how to assess the present performance of the research councils. The accompanying chart, based on figures taken from the Merrison report, shows the use made of resources in 1978-79 by the four research councils supporting research in the natural sciences. The cost of commissioned research is that commissioned by government departments from the research councils under the Rothschild customer-contractor principle.

The pattern of spending by the Science and Engineering Research Council is anomalous in that, of the £144 million claimed as university support in 1978-79, only £51 million was spent directly in universities, with the remainder divided almost equally between service laboratories and subscriptions to international projects.



Research council spending, 1978-79. Spending by the Agricultural Research Council (ARC), Natural Environment Research Council (NERC), Medical Research Council (MRC) and Science and Engineering Research Council (SERC). Source: Cmnd 8567, HMSO.

For the committee (which will have met for the first time this Wednesday, 4 August), the most difficult task will be to establish criteria for deciding how the "right" balance between in-house research and university support should be struck. The chairman of the committee is thought to be impartial in the sense of being as impatient with the research councils as with academics.

Telecommunications

Battle hots up

Mercury, the private telecomminications network licensed last year in Britain to compete with British Telecom, the still-public network, is about to take off rather sooner than expected. Its founders (Cable and Wireless, British Petroleum and Barclays Bank) have brought foward to next spring the launch of a service in London, intended as the first element in a more extensive network.

Mercury says that demand from potential customers is the chief reason why its plans have been advanced, but there seems no doubt that the competitiveness of British Telecom is another. At the outset, Mercury hopes to gain some advantage because it will be offering high-speed digital transmission services, available from British Telecom only in the City of London. The plan is to do for Birmingham by next May what will have been done in London a little earlier, when the two cities will be linked by microwave. These two services are the first elements in what Mercury misleadingly calls a national network. The present goal (for 1984) is a figure-of-eight network linking only the major commercial cities in central England. Initially transmission within cities will be by microwave radio.

Initially, Mercury will be suitable only for customers wishing to send voice and data down leased lines at 64 kilobits or 2 megabits a second. Charges will be based on standard rates per channel, independent of distance. The basic network is expected to cost about £50 million, but the capital cost of providing a network to compete with British Telecom's will be far more. Investment of £1,000 million over 25 years has been mentioned to pay for, among other services, switching and possibly a link with British Telecom.

But plans for the future will depend on customer demand. Mercury is in touch with 25 potential customers for its London service, and government departments as well as large companies are said to be showing interest. Mercury believes that its chief attraction over British Telecom's digital service in London will be its transatlantic satellite-link. At one stage, plans for international links had seemed doomed to be obstructed by British Telecom which, as the signatory to Intelsat, is the recognized international carrier. But Mercury, which will be negotiating directly with Intelsat to carry traffic late next year from London, is unperturbed that British Telecom must sign the contract, seeing British Telecom's involvement as purely administrative.

How successful Mercury is in attracting its statutory allowance of 3 per cent of British Telecom's business by 1985 will also depend on the competition. The consensus is that the monopoly is putting the heat on. **Judy Redfearn**

UK higher education

Call for change

A gang of lounge-suited revolutionaries issued last week a call to turn the British educational system on its head. Calling itself a study group of the Royal Society of Arts, and concealing its subversive message* in glossy covers decorated with an elegant engraving of the Adam building used as its accommodation address, the gang demanded nothing less than the reorganization of the Department of Education and Science (to include industrial training), tax deductibility for fees paid for technological education, the reform of the British school examinations system and a scheme for supporting institutions of higher education with public funds on a scale determined by "the funds which institutions succeed in raising for themselves".

The movement's front-man, and self-confessed chairman of the study group, is Sir Henry Chilver, vice-chancellor of Cranfield Insitute of Technology and chairman of the British government's Advisory Council on Applied Research and Development (ACARD). Sir Henry is widely tipped in Whitehall as the man most likely to succeed Sir Alec Merrison (vice-chancellor of the University of Bristol, chairman of the Advisory Board for the Research Councils, chairman of the council of CERN, etc.) as the chairman of most committees on British science policy during the 1980s.

Speaking last week to journalists (outnumbered two to one by members of the group), Sir Henry admitted that the manifesto called for a revolution in the British educational system. He said he would be infiltrating some of the proposals into ACARD's deliberations on the mechanisms for supporting British university research. The group hopes to accomplish its goals by putting pressure on politicians and civil servants, and by writing letters to influential people.

All-purpose chairman, Sir Henry Chilver

One objective is to change the education of young people aged 16–19, providing them with "flexibility of employment opportunities". The manifesto also demands a "shift in curriculum for 13–16 year olds", a new school examinations system "aimed at encouraging young people to be educated for their future capability in society" and the monitoring of "the effectiveness of education for wealth creation" by some method as yet undisclosed. To accomplish these objectives, the group admits, it would be necessary to rewrite both the Education Act (1944) and the more recent Training Act so as to give a new Department of Education and Training direct control of the education of the young.

There seems, however, to be an ideological split among the members of the group on central direction for higher education. One member, Dr Donald Moore (previously with Imperial Chemical Industries Limited), said that "a lot of money is wasted in universities" and called for strong central management of higher education. But Chilver seems to prefer a system of financial incentives to make universities more aware of industrial needs.

The most subversive proposal is that for replacing the present general subsidy of higher education with a system in which universities and other institutions would be supported on some scale related to the resources they had been able to recruit from industry and elsewhere. The manifesto says that "those most closely related to industry would attract continuing public support" but otherwise conceals its reasons for believing in a switch to "geared funding" and the means by which that would be accomplished, on the pretext of "keeping it short". **John Maddox**

Nuclear aftermath

Euthanasia plan

The Soviet media — not normally practitioners of sensation journalism — last week gave major coverage of alleged British plans for "selective treatment" and/or enforced euthanasia of victims of a nuclear disaster. According to the Soviets, plans prepared by the Royal College of Physicians for the British government insist that "anyone who is seriously injured must be destroyed" — preferably by the military or the police, since the doctors, allegedly, are unwilling to break the Hippocratic oath.

These remarkable reports are apparently based on an article in *The Guardian* of 22 July. Within three days it had been picked up by *Pravda* and then by Moscow Radio — remarkably fast for Soviet journalism.

The *Guardian* writer, Andrew Veitch, says that his story was based on "classified" government plans leaked to his newspaper and a "statement" prepared by the faculty of community medicine of the Royal College of Physicians. This statement, he says, was never published.

Acccording to the faculty members, however, the document to which Mr Veitch referred was never, in any sense, an official statement. It was, they say, simply a discussion paper written by a small "study group" which the faculty board felt itself, as a body, unable to accept.

The president of the faculty, Professor Alwyn Smith, who is also a signatory of the recent "Physicians against Nuclear War" declaration, describes the original paper as "somewhat forthright" and suggests that it would need "very extensive revision" before it would gain the support of the faculty's membership. It is presumably the latest version of this document, which was discussed last April at the faculty's meeting on medical planning in relation to nuclear war, that came into the hands of Andrew Veitch.

Since the speech of Mr Andrei Gromyko at the United Nations Disarmament Session in June, the Soviet media have repeatedly attacked the reluctance of Western governments to respond to Soviet "peace initiatives".

To that extent, their response is predictable. The curious error by which the study group's draft document, which called for a full public debate of the issues (including euthanasia) involved in disaster planning, becomes in the Russian version a secret government document prepared by "troglodytes from the world of medicine" and kept secret from the British people, must inevitably throw some doubt on the Soviet understanding of the Western-style nuclear debate. **Vera Rich**

Repression in Guatamala

Physician freed

A prominent Guatemalan physician and anthropologist, Dr Juan José Hurtado Vega, was released from government custody last Thursday after enquiries by a delegation from five US scientific societies.

Dr Hurtado had been held virtually incommunicado, and without charges, since 24 June, when he was abducted by armed men in civilian clothes outside his clinic in Guatemala City. Not until 4 July, in a speech by Guatemalan President Efrain Rios Montt, did the government admit that Dr Hurtado had been arrested.

According to the American Association for the Advancement of Science (AAAS) Clearinghouse on Science and Human Rights, Dr Hurtado was released to the custody of the International Red Cross Committee, which suggests that he was in need of medical treatment. The members of the US delegation that visited Guatemala to enquire after Dr Hurtado told reporters upon their return last week that they were seriously concerned that he had been physically mistreated and possibly tortured. Dr Hurtado's wife reported that during the five-minute visit she was allowed to her husband — a visit that was filmed and broadcast by the state-run television — she noticed that he was very weak, had lost a lot of weight and had a haematoma on his arm. The delegation was told by Guatemalan officials that Dr

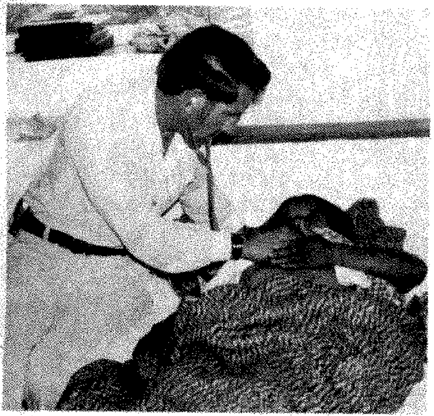
0028-0836/82/310508-02$01.00

Hurtado was in good health and was recovering from a gastro-intestinal illness. AAAS said that Dr Hurtado and his wife were going to leave Guatemala and were due in the United States within a few days.

The reasons for Dr Hurtado's arrest remain unclear. President Rios Montt, in his television address on 4 July, accused Dr Hurtado of being a communist; later, in an interview with a BBC correspondent, Rios Montt charged that "he is not merely a communist but a captain of many units, a member of the leadership group. His son, all his family have been killing people." The US delegates reported that many government officials they spoke to brought up the association of one of Dr Hurtado's daughters with the communist insurgents. She is now living in Nicaragua.

Dr Hurtado may also have come under suspicion for his work among the rural poor. Since 1976, he has run a private clinic offering free health care in San Juan Sacatepequea, an Indian village outside Guatemala City. The delegation doubted that this was the principal factor behind his arrest, especially since the government has made no effort to shut down the clinic.



Dr Hurtado and patient

The most likely direct motive for his arrest may have been the kidnapping, the day before, of the Interior Minister's son by the Guatemalan communist party. The Interior Minister, or perhaps even a subordinate acting on his own, may have ordered the arrest of Dr Hurtado as a hostage. If so, it was apparently a miscalculation: when the communists issued a list of prisoners whose release they were demanding, Dr Hurtado's name was not on it.

The US delegation, which comprised AAAS, the American Public Health Association, the American Anthropological Association, the National Association of Social Workers and the Institute of Medicine of the National Academy of Sciences, expressed concern that this case may be a bellwether of a return to the repression of the previous regime in Guatemala. President Rios Montt, who came to power in March of this year, pledged to restore civil rights and constitutional law. On 1 July, however, the government declared a "state of siege", suspending all political activity and most civil liberties.

Stephen Budiansky

Plea from a Soviet refusnik

An open letter to Dr J.M. Legay, Secretary General of the World Federation of Scientific Workers.

SIR — Several times either alone or together with colleagues in the same position (having been refused permission to leave the Soviet Union), I have appealed to you and to the World Federation of Scientific Workers for help. But only recently have we received a reply — and that not directly, but in the pages of *Nature* (11 February, p.452). I regret to say that your answer was both surprising and disappointing. Being absolutely distressed by it I have to address you once again. Another, perhaps more important reason making me do it is that I am sincerely convinced of your honesty, humaneness and high moral standards — anything else would be incompatible with the high position you occupy. Besides, I believe that the contents of your answer suggest that you are not aware of the gravity of the situation of the scientists refused permission to leave the Soviet Union.

For more than 3 years I and my friends have been trying, through completely legal channels, to obtain permission to leave the country. All of us after many months of waiting have been refused permission and in most cases nobody took the trouble of explaining to us the reasons for this refusal. And none of us has ever dealt with military or state secrets. That is why I say that these refusals do not comply with the laws of the Soviet Union, with the International Human Rights Declaration and with the Helsinki Final Act. The only reason for these refusals is the fact that we have scientific degrees. And it has nothing to do with the problem of the notorious "brain-drain" since most of us are deprived of any professional work and have been deprived of it ever since we applied for permission to leave the USSR.

I have appealed more than 20 times to different Soviet bodies to cancel the illegal decision and to protect me from lawlessness but I have not received a single answer and the experience of many of my colleagues has been the same. Neither have I received any answer from the vice-president of the World Federation of Scientific Workers Mr N.N. Inozemtsev or from Mrs Janushevaskaya. But according to the federation's charter, it is their duty to defend the interests of scientists.

Addressing you, Mr Legay, I like many others expect sympathy and help. Maybe it is naive on my part but I consider it your moral duty and that of the federation to help us. It is not a question of me alone, a whole group of scientists is involved. It is not only our careers as scientists, but our whole lives that are threatened. We suffer material hardships and nervous stress beyond any normal limits. We are beginning to break down. Recently one of us, Dr Tsipkin, died after receiving a dismissal notice. Many of us have become seriously ill — and still we have to support aged parents or our children. We are in complete isolation, we are thrown out of society and in fact are not protected by law. And all this for one "fault", for one "crime" — our wish to leave the Soviet Union.

We are living in the world so strikingly depicted by Kafka, but the circumstances of our life are much harder than those of his characters. We have no possibility in our own country to protest openly, publicly. We can't defend our interests legally. We can hope only for help from our western colleagues. This is our only hope, the only thing that makes it possible for us to go on living.

Don't become a silent accomplice of the injustice, don't let evil take the upper hand, raise your voice for us. I want to believe, Mr Legay, that an appeal from you to the Soviet government, an appeal from the World Federation of Scientific Workers and from its journal *Scientific World* will change our position, will make it possible for us to leave the Soviet Union and to return to scientific work. Don't let our appeal get drowned in bureaucratic hold-ups and procrastinations.

Only an appeal to the Soviet government can change the situation. The more definite, the more public your stand, the sooner it will help the unfortunate. Take this stand, Mr Secretary General, and like any noble deed it will only add to your and the federation's authority.

You cannot but understand, Mr Secretary General, that our life and our fate have become part of an important problem — that of trust among scientists and their mutual understanding. You have to understand that the question of mutual trust and respect, the questions of scientific contacts will depend on the settlement of our problem. It cannot be right to let general and undoubtedly very important problems obscure the fates of individual people. It cannot be allowed that behind a torrent of beautiful words evil should be committed. Who but the World Federation of Scientific Workers and its head can realize and know it? Who but the federation and its Secretary General can and must stand on guard defending the members deprived of everything?

Moscow J.S. IRLIN, DSci

CORRESPONDENCE

Imperial echoes

Sir — Your note on the establishment of Imperial College's Centre for Biotechnology (*Nature* 24 June, p.617) has caught the sentiment of the occasion, but lacks one or two points of detail.

Imperial Biotechnology Ltd (IBL) is jointly owned by Imperial College (35 per cent), TDC Developments Ltd (35 per cent) and its own staff, who hold the balance. The fermentation pilot plant will be managed by IBL, which will expand the business of development and pilot scale manufacture of specialized biological products. The company and the college are fully committed to maintain and expand the current college teaching programme. They have made a teaching agreement for the provision of adequate pilot plant and fermentation facilities for the college's programme of work. Like any other customer, the college may buy additional resources for research purposes from the company above the agreed level.

Resources that were absorbed by the non-commercial pilot plant operation may now be released for academic purposes; the college is applying part of them to the two lecturer posts shortly to be advertised (the Leverhulme chair is financially self-contained). The lecturers' positions will not therefore be so precarious as the comment ". . . salaries will be met by the fees earned from contracts with outside bodies" implies. They will be normally established posts.

The Centre for Biotechnology sees contract work as a major factor in the development of its research programmes — biotechnology is nothing if not an applied discipline. However, a substantial proportion of the investment in the centre must come from Imperial College's own efforts — unless the college clearly demonstrates its commitment to the subject, the centre will lack the credibility it needs amongst its potential customers.

Imperial College has found what it believes to be a workable combination of commercial risk and academic purposes that suits its own particular circumstances. It is firmly committed to producing the people and the products needed by the biotechnology industry by these means.

David Thomas

Meltdown risks

Sir — Robert J. Yaes has overstated the hazard of a major nuclear accident by two orders of magnitude in his letter of 24 June (*Nature*, p.622). Not even a meltdown in midtown Manhattan could produce the "several million" deaths he envisions. The number of fatalities from a "maximum credible" accident, which the US Nuclear Regulatory Commission has estimated would occur once in 100,000 meltdowns, is put at 45,000. This is comparable to the toll that might be expected from such "conventional" hazards as oil and gas explosions, and *one-fourth* the number of deaths that could occur if a certain major dam in the Southern California earthquake fault zone should break.

Dale H. Gieringer

Stanford, California, USA

Not by mirrors

Sir — In *News and Views* of 28 January (p.277), Jared Diamond discussed the occurrence of migratory birds in places outside their normal geographic range (vagrants)[1]. Such vagrancy has been noted in many parts of the world and a variety of hypotheses have been put forward to account for it. By discussing only the ingenious "mirror-image misorientation" hypothesis of DeSante[2], Diamond erroneously implied not only that it is the proven mechanism underlying the occurrence of vagrant warblers in California but also that it can account for vagrancy on a worldwide basis.

Based on the hypothesis that some individuals in a population of migrants make mirror-image orientational errors (such as heading SW instead of SE in autumn), DeSante predicted the relative frequency with which various species should occur. The pattern of records supported the hypothesis. The blackpoll warbler (*Dendroica striata*), which migrates towards the SE over North America in the fall, is the most numerous vagrant on the California coast. *A priori*, one would expect warblers captured off coastal California to show SW hopping in an orientation cage. DeSante tested blackpolls captured on the Farallon Islands off California. Unfortunately, almost none of the birds oriented toward SW; most mean directions were toward NE or NW. The results could be explained only by the *a posteriori* hypothesis that the birds have four preferred directions: the normal SE heading, the SW mirror-image, and the reverse of these two. The data, therefore, do not provide strong, clear support for the original hypothesis.

The mirror-image misorientation hypothesis is important and deserves further testing. It is premature, however, to regard it as proven or to extend it to other areas of the world. There are data to suggest that weather patterns, especially wind, may play a large role in bringing vagrants to California and other areas[3]. Recently, a strong association between the arrival of vagrants and particular wind patterns has been demonstrated in Great Britain. Interestingly, the blackpoll warbler is the most numerous warbler vagrant from North America, a fact very difficult to account for by mirror-image misorientation[4].

Prions have feathers

Sir — In *News and Views* on 13 May[1], R.H. Kimberlin discusses S.B. Prusiner's recent suggestion in *Science* that scrapie is caused by some new sort of proteinaceous infective particle or "prion", to use the acronymic neologism suggested by Prusiner[2]. However, there can be no doubt that prions exist. They contain lots of nucleic acid, packaged in a wonderful variety of proteins. One of the more striking of the proteins is keratin, arranged in a complex structure, the feather, that enables the prions to maintain their temperatures well above ambient and to flutter above the southern oceans.

Today the prions are placed in the genus *Pachyptila*. Their vernacular name stems from the generic name given by Lacépède, after the serrated edge to the birds' mandibles (*πριων*, a saw). It was in use as an English name among ornithologists in the last century[3] and is given in the *Oxford English Dictionary*.

Perhaps in this case there is little chance of confusing the old and new meanings of the word. But precision and unambiguity are important in science — even if they are not in *Science*, whose editors do not wish to point out this unfortunate homonymy to their readers. I hope you will be more concerned and that *Pachyptila* will in future be the only prion to appear in *Nature*, whether or not "proteinaceous infective particles" occur in nature.

The parasitic balance

Sir — I am sure Professor Cox does not need me or anyone else to defend him, but Dr Palmieri's letter (*Nature* 15 July, p.220) does not seem to take account of the fact that Cox's original report (*Nature* 4 March, p.10) was an account of a symposium specifically devoted to *diseases* caused by parasites. Aside from this, of course, Palmieri's contention is true — most parasites are in balance, albeit maybe a delicate balance, with their hosts.

Notable examples are found amongst parasites of wild animals, in this country and elsewhere. Flagellates and sporozoans are almost ubiquitous amongst the wild vertebrates of this country, but direct pathogenic effects of their presence are rare. This does not necessarily mean, however, that such infections are not subtly harmful in conditions of unusual stress, or by virtue of immunodepressive effects. A deeper understanding of factors involved in maintaining the balance might help explain why it sometimes breaks down, with devastating effects among the host population, as exemplified by recent epidemic sleeping sickness (human trypanosomiasis) in parts of Africa.

Philosopher in gaol

Sir — I have received first-hand information concerning Professor Lessek Novak from the University in Poznan, a distinguished philosopher in Poland's strong tradition of logicians. He has been confined for seven months, held in a prison without daylight and infested with bugs. Professor Novak took part in the postgraduate courses at the Inter-University Centre in Dubrovnik and has been very active in international collaboration in science. His confinement is a grave violation of human rights, particularly that of freedom of thought. I appeal to the scientific community to do everything possible to bring about his liberation.

The NK cell: a phagocyte in lymphocyte's clothing?

from Bernard M. Babior and David W. Parkinson

ANIMALS under attack by invading microorganisms are able to kill their attackers by means of a group of exceedingly powerful oxidizing agents which are mobilized in response to the microorganisms' invasion. The earliest evidence for the existence of this oxygen-dependent killing system was reported some 20 years ago by Karnovsky[1] and by Quastel[2]. Since then, this system has been investigated in many laboratories (for reviews see refs 3,4), and it is now understood at least at an elementary level.

The critical step in the mobilization of the lethal oxidizing agents is the activation of a membrane-bound enzyme (or enzyme system) known as the 'NADPH oxidase'. This oxidase is dormant in an unstimulated cell, but comes to life when the cell encounters a microorganism. As its name suggests, the oxidase catalyses the transfer of electrons from NADPH to oxygen. What is unusual about this reaction is that the oxygen is reduced, not by two electrons to form H_2O_2, but by one electron to form the superoxide radical ($O_2^{\cdot-}$).

It is from this innocuous $O_2^{\cdot-}$ radical that all the system's lethal oxidants are formed. These oxidants include hypochlorite (OCl^-), known commercially as a powerful disinfectant, and a group of highly reactive oxidizing radicals, including the hydroxyl radical ($OH^\cdot$), one of the most reactive compounds known in chemistry. OCl^- arises through the peroxidase-catalysed oxidation of Cl^- by H_2O_2, which in turn is formed by the dismutation of superoxide ($O_2^{\cdot-} + O_2^{\cdot-} + 2H^+ \rightarrow H_2O_2 + O_2$), a very rapid reaction which consumes most of the $O_2^{\cdot-}$ manufactured by the cell. $OH^\cdot$ and the other reactive oxidizing radicals are made from the remaining $O_2^{\cdot-}$; the mechanism of their production is poorly understood apart from the fact that no peroxidase is required, though an iron-catalysed reaction between $O_2^{\cdot-}$ and H_2O_2 ($O_2^{\cdot-} + H_2O_2 \rightarrow OH^\cdot + OH^- + O_2$; the famous Haber–Weiss reaction) has been proposed as the source of the hydroxyl radical. It is a striking illustration of the versatility of biological systems that they are able to manufacture and put to use compounds as reactive and dangerous as OCl^- and $OH^\cdot$.

Until now, the oxygen-dependent killing system has been thought to be restricted to 'professional phagocytes' (granulocytes and mononuclear phagocytes), the front-line cells whose purpose in life is to engage and destroy invading pathogens. In this issue of *Nature* (p.569), however, Roder and his associates show for the first time that the same system is expressed by a lymphocyte. The lymphocyte that acts like a phagocyte is the natural killer (NK) cell.

The NK cell is a large lymphocyte whose most prominent morphological feature is a single large granule in its cytoplasm[5]. Many biological roles have been proposed for this enigmatic cell, both from experiments testing the effects of partially purified NK cell preparations on various targets[6] and from studies with intact NK-deficient animals and humans[7]. A function in host defense against infection has been postulated on the basis of the NK cell's ability to recognize and kill virus- and parasite-infected target cells. Its capacity to kill certain malignantly transformed cells has led to speculation about its participation in defense against cancer. Finally, it is able to kill certain types of cells in the normal bone marrow and thymus, suggesting that it may serve to control the function of these tissues on a day-to-day basis. The true physiological role of the NK cell, however, is still not fully understood. Even less well understood are the means by which it exerts its diverse effects. In particular, basic questions as to how target cells are recognized and destroyed are largely unanswered.

The work of Roder and his associates now appears to provide a partial answer to at least one of these questions. The ability of the NK cell when exposed to a susceptible target to produce $O_2^{\cdot-}$ (in staggering quantities too; the amount of $O_2^{\cdot-}$ manufactured by these cells can exceed by two orders of magnitude the amounts liberated by fully stimulated neutrophils or monocytes) and to use this $O_2^{\cdot-}$ to kill this target strongly implicates some form of the oxygen-dependent killing system in target cell destruction. This system must comprise more than just $O_2^{\cdot-}$ itself, because NK cells from patients with Chediak–Higashi disease exhibit greatly impaired killing ability despite a normal $O_2^{\cdot-}$-generating response to NK-susceptible targets[8]. The hallmark of Chediak–Higashi disease is the swollen, grotesquely misshapen lysosome that is found in the cells of affected subjects; perhaps the granule of the NK cell is another participant in its oxygen-dependent killing system, and it is the malfunction of this granule that accounts for the defect in NK cell activity in Chediak–Higashi disease. Supporting this notion are recent experiments with metabolic inhibitors which have been interpreted in terms of a 'stimulus–secretion' model of NK cell activity[9], consistent with the morphology of the cell as a large lymphocyte containing a granule which, after all, must be there for a reason.

Like all novel discoveries, the finding that NK cells can kill with oxygen raises more questions than it answers. Is NK cell function impaired in chronic granulomatous disease, the inherited disorder in which phagocytes are unable to manufacture their lethal oxidants[3]? What are the other components of the oxygen-dependent killing system of the NK cell? Does the NK cell possess oxygen-independent killing mechanisms like those described by Elsbach in the rabbit and human neutrophil[10]? What do these findings say about the relationship between the NK cell and other types of lymphocytes, some of which have killer activity of their own? Is the NK cell a true lymphocyte, or is it nothing but a phagocyte in lymphocyte's clothing? □

The fifth major D/V *Challenger* operation in central equatorial waters

from the Scientific Staff, Leg 85, DSDP/IPOD

On 2 May 1982 the drilling vessel *Glomar Challenger* arrived back in Honolulu from Leg 85, the fifth major operation of the Deep Sea Drilling Project in the eastern and central equatorial Pacific. In her holds were well over 2 km of central equatorial sediments and 1.6 m of basalt, the products of 16 drill holes of which the deepest had reached to 525 m below the ocean bottom. From this material, some 21,000 samples have now been distributed to the scientific party aboard and to collaborators all around the world. Some preliminary conclusions, discussed below, have already been reached but ahead lies the main analysis of the core material. The ultimate aim is to understand the entire equatorial system, its behaviour through time, its reaction to stimulation from outside, its effect on and control of climate, and its feedback mechanisms.

The central equatorial Pacific has always been a primary target for DSDP drilling. Earlier legs (Fig. 1) had helped establish the global Tertiary tropical biostratigraphy and chronology that have shaped our understanding of past oceanographic events, and the development of tectonic models for the Pacific Plate. Tertiary equatorial sediments are very sensitive recorders of the interplay between tectonism, oceanic circulation patterns, fluctuations in biological productivity, dissolution and, ultimately, diagenesis.

In the past, drilling disturbances, particularly in the upper unconsolidated 100–300 m of sediments that often comprise much of the Neogene, have hampered really fine-scale reseach in sediments beyond the reach of conventional piston coring. Leg 85, with relatively new tool at its heart — the hydraulic piston corer — was designed to respond to the growing need to obtain environmental signals with frequencies measured in 10^3–10^4 yr.

The hydraulic piston corer (HPC) was developed by DSDP during the late 1970s and first successfully used during Leg 64 (1978); the HPC is a pressure-activated 9 m long piston coring device (with a 5 m option) which is lowered to the bottom of the drill string. It allows the recovery of successively deeper 9 (or 5) m sediment cores in sufficiently soft layers, without having to resort to rotary drilling. The disturbances that make rotary-drilled samples of softer sediments almost useless for high-frequency analyses are thus avoided.

The Joint Oceanographic Institutions for Deep Earth Sampling Ocean Palaeoenvironmental Panel designed Leg 85 to recover undisturbed, tropical Cenozoic sections for research on: (1) high-resolution bio-, magneto-, seismic-, carbonate and stable-isotope stratigraphy; (2) oceanographic and biological (evolutionary) changes associated with the Eocene–Oligocene boundary; (3) termination of Atlantic–Pacific circulation across the Central American isthmus and the evolution of modern Pacific circulation; (4) the origin of the fine-scale cyclicity seen in Pacific sediments of Oligocene to Quaternary age; and (5) carbonate and silica diagenesis in thick biogenic sections. In order to ensure the highest possible resolution and to avoid coring gaps, each hole was doubly piston-cored and then rotary-drilled to basement through the stiffer sediments below the reach of the HPC (generally 150–250 m sub-bottom).

Five sites, 571–575 (Table 1, Fig. 1), were drilled by Leg 85. With the exception of Sites 571 and 572 (Site 572 is a repeat of Site 81, of DSDP Leg 9), which were to terminate in the Miocene, latest Eocene was anticipated to be the basement age at all the sites. Thus, it was also hoped that complete, or near complete, records of the very 'elusive' Eocene–Oligocene (35–40 Myr) transition could be recovered.

Geologically, the dominant tectonic feature of the central–eastern Pacific region is the East Pacific Rise, which generates new oceanic crust at rates of 8–20 cm yr^{-1}, and which serves as a boundary to the Pacific (on which all the Leg 85 sites lie), North American, Cocos and Nazca Plates. In simple terms, during the past 50 Myr, new Pacific crust has been continuously spreading northwestwards, away from the East Pacific Rise. As it spreads it subsides from a depth of about 3,000 m. The motion has two crucial results: it continuously alters the relationship between the stationary equatorial high-productivity belt above and its depositional expression on the sea floor (Fig. 1), and the subsidence with age and cooling of the spreading crust brings about an increasing exposure of solution-susceptible calcium carbonate produced by plankton to deeper, more corrosive waters.

Biological processes are superimposed on this evolving tectonic framework. Upwelling associated with the equatorial current system creates, along the equator, a fertile planktonic belt of variable width (today 3–4° wide and having its maximum expression slightly offset to the north of the Equator) and dominated by carbonate and silica production.

Assuming that these present-day relationships between surface waters and productivity have remained roughly constant during the Cenozoic, a broadly lens-shaped body, with its apex offset to the north, of dominantly biogenous calcareous–siliceous sediments should have accumulated in this region. It should be dominated by calcareous sediments along its crest and be increasingly more siliceous towards its northern and southern flanks — as indeed has been confirmed by seismic profiling, piston coring and

Table 1 Summary of Leg 85 coring

previous DSDP drilling.

The product of this simple tectonic-productivity model of the equatorial region is further altered by changes in oceanographic conditions. The latter affect primarily solution of calcium carbonate or may, in the form of thermohaline bottom currents, physically remove and mix sections of the depositional record. Whereas solution of biogenous silica appears to be occurring throughout the water column, calcium carbonate is very responsive to changes in the corrosiveness of deeper waters. At the other end of the spectrum, numerous submarine outcrops of Tertiary sediments and the widespread hiatuses occurring in the equatorial Pacific testify to the effectiveness of bottom-water erosion throughout the Cenozoic.

Shipboard analyses made during Leg 85 obviously cannot do justice to the massive amount of data gathered but preliminary impressions indicate that of the factors affecting the Leg 85 drill sites, the most striking is the strong east–west productivity gradient. At Site 572, which is at 114°W, sedimentation and accumulation rates are extremely high (often 50 m Myr^{-1}). The sedimentation rate curve at Site 573, 2,100 km to the west, has the same shape as that at 572, but quite attenuated rates (except for the Plio-Pleistocene). Although depth and latitude also contribute to the differences between Sites 572 and 573, analyses of the carbonate and non-carbonate accumulation rates, foraminiferal dissolution index, and qualitative evaluation of diatom and benthic foraminiferal species distributions all support a strong east–west productivity gradient during the mid-Miocene to early Pliocene. This gradient is dominated by the production of siliceous microfossils (mostly diatoms) in the east and the observed lithological and stratigraphical variations appear to respond to this siliceous east–west gradient.

The increasing influence of silica productivity in the east is also indicated by a comparison of the carbonate and non-carbonate accumulation rates. (For all of the Leg 85 sites it is valid to assume that the non-carbonate fraction is mostly comprised of biogenous silica and that there is a consistent association of diatom species, indicative of upwelling, with times of increased non-carbonate accumulation.) At Site 572, a plot of carbonate rate increases positively and linearly with non-carbonate rates. At Site 573, 20° to the west, a comparison of the post-Oligocene carbonate and non-carbonate accumulation rates reveals a similar positive relationship but with a depressed slope,implying that the non-carbonate component decreases its dominance over deposition.

The influence of the east–west gradient of decreasing productivity is particularly noticeable when comparing accumulation rates, carbonate content and foraminiferal dissolution index curves between Sites 572 and 573. At Site 573, the carbonate and non-carbonate accumulation rate and carbonate contents follow one another nicely, high carbonate values being associated with high accumulation rates (productivity) and better preservation. In contrast, at Site 572, the more easterly site, the same relationships are found only during periods of relatively lower accumulation rates; times of high accumulation are associated with enhanced dissolution and decreased carbonate content. The explanation may lie in the magnitude of non-carbonate accumulation at each site: the highest non-carbonate rate at Site 573 is about 0.5 g per cm^2 per 1,000 yr, whereas the maximum value at Site 572 is almost three times higher. This suggests that, when a certain non-carbonate accumulation rate (productivity) threshold is reached, the abundant organic matter produces steep dissolution gradients and enhanced dissolution. We only see evidence for this phenomenon at Site 572, but the implications for palaeoceanographic modelling are intriguing. □

Protein folding by numbers

from Roger Pain

It has long been accepted that the folding of globular proteins from linear unstructured polypeptide chains must occur along closely defined pathways, so that the rate of folding can keep pace with the rate of biosynthesis. Proof of the existence of pathways has, however, been harder to come by. Experimental evidence is required of the identity of species intermediate between the fully unfolded and native states and, more precisely, of three of their properties. The structure of the intermediate, the rates of interconversion with other states and proof that the intermediate lies on the folding pathway and is not an artefact of the denaturation conditions must be obtained to characterize the part of the folding pathway associated with the intermediate under study.

In two recent papers (*J. molec. Biol.* **157**, 331 & 357; 1982), Labhardt has demonstrated the existence of four non-native states associated with ribonuclease, has studied the kinetics with which some of them are formed and has interpreted these results in terms of a sequential mechanism of folding in which a relatively stable β-sheet structural intermediate plays a rate-determining role.

Some may find it surprising that a fresh contribution about protein folding can be extracted from a study of the old biophysical workhorse, ribonuclease A (RNase A), using the relatively low-level information techniques of far-UV circular dichroism (CD) and tyrosine absorbance. Ribonuclease is classed as an $\alpha + \beta$ protein as its three-dimensional structure contains both α-helix and β-sheet secondary structures which are located in no regular orientation with respect to each other. It is peculiarly attractive as a model for folding studies because it can be cleaved specifically between residues 20 and 21 to give the S-peptide, which contains the elements termed α_1, and the S-protein, which contains elements β and the remaining α structure, α_2. The S-peptide and S-protein will combine spontaneously to give enzymatically active RNase S in which the two moieties undergo mutual stabilization of their secondary and tertiary structures.

There are thus three stable species, RNase A, RNase S and S-protein, whose structural relationship to each other is precisely known from X-ray crystallography. These have been partially denatured variously by heat, acid and guanidinium chloride, and the contents of α-helix and

β-pleated sheet in the products estimated with care from the far-UV CD spectra.

Labhardt correlated these results with the known structures of the three starting products so that he could identify four distinct products of unfolding. In terms of the three main regions of secondary structure, these are $\alpha_1\beta$, $\alpha_2\beta$, β and α_2^*. $\alpha_1\beta$ is not stable but may have a role as a folding intermediate, while α_2^*, which represents the occurrence of an α helix in the thermally unfolded state, cannot yet be assigned to a definitive structure and hence to a role on the folding pathway.

These experiments on the equilibria of the various unfolding reactions of ribonuclease and its derivatives, together with supporting data from the literature, lead to the conclusion that the three antiparallel strands of folded β-structure must be formed for the N-terminal helix (α_1) to be stabilized. However, the species $\alpha_1\beta$ requires the further independent folding and tertiary association of the α_2 group of helices to give it permanence as $\alpha_1\alpha_2\beta$ (RNase A or RNase S). Thus in the folding molecule, three different regions of secondary structure can form independently and associate with mutual stabilization to give the folded enzyme with its native structure and function.

Given some of the structural intermediates associated with the folding pathway, in what order do they form and associate and what are the rate-limiting stages? Labhardt goes on in a second paper in the same journal to monitor the kinetics of refolding of RNase S by the regain of 2′-CMP binding ability and, with identical results, by changes in tyrosine absorbance. The kinetics are, as we would now expect for a proline-containing protein (see *Nature* **290**, 187; 1981), complex. Three phases are resolved in refolding from initial conditions in which different proportions of the equilibrium species reported above have been shown to exist. Two interesting features emerge. The fastest phase is second order, reflecting the rate-limiting association of S-protein and S-peptide, and the amount of product, RNase S, formed from this phase is equal to the amount of S-protein with preformed structure existing in the initial conditions from which folding takes place. Thus, this particular part of the structure, and not, for example, the α_2 moiety, is essential and sufficient for the productive association with S-peptide to take place. It is a key intermediate on the folding pathway.

The two slower phases of refolding reflect the same folding pathway but starting a stage further back, that is from S-protein molecules whose β-structure is unfolded. These may collapse to a condensed species containing improper proline isomers which have to isomerize before the fully native structure is attained (species I in *Nature* **290**, 187; 1981). Labhardt's second key observation is that the rates of these two slower phases are linearly related to the thermal stability of RNase S in the final conditions of the folding experiments. Since the S-peptide has no direct effect on these kinetics, it is concluded that the species whose thermal stability dictates the rates of folding is the condensed structure with improper prolines. This is therefore identified as a transient precursor of the folded S-protein with its β-structure.

This work represents a significant clarification of intermediate species involved in the folding of ribonuclease. Structures which can be 'seen' by available techniques can be numbered and ordered into an overall sketch. However, just as painting by numbers does not result in a work of art, so folding by numbers does not give us the complete folding picture and there still remains much to be discovered. ☐

Measuring competition in plant communities

from Peter D. Moore

EXPLANATIONS of how similar species can coexist within a single area have, in general, been more satisfactory when dealing with animal species than with plants, and it is fairly evident why this should be. Animal species vary in their specific demands for food resources and may also vary in the manner in which they tap those resources, hence there is considerable opportunity for niche specialization and co-adaptation between species. In the case of autotrophic plants, there would appear to be far less room for diversification. All the various grass species in a meadow are basically doing the same things — gathering light energy, reducing carbon dioxide from the atmosphere, extracting water and required elements from the soil. Just how can so many morphologically similar species coexist? Is their coexistence accompanied by fierce competition for the habitat's resources, or has the process of niche specialization over evolutionary time scales resulted in competition interactions being minimized?

Such questions have great appeal to ecological theoreticians[1-3], particularly to animal ecologists who can base their models on the Lotka–Volterra population growth equations. Newman[4] has recently emphasized that this approach, which depends on the numerical assessment of populations, is not entirely satisfactory when applied to plants, in which vegetative proliferation of individuals can occur. He develops two alternative models more appropriate for plant studies, and concludes that the maximum number of plant species which could coexist with respect to a single habitat axis is two or three. But one is left with the problem of how many 'axes' are present within a habitat. Taking a proposed habitat with six niche axes, for example, and assuming a limitation of two species per axis, Newman's model permits the coexistence of $2^6 = 64$ species within the habitat, provided that all possible axis combinations are possible, that is, that the axes are non-related.

Theoretical models may be pleasing to the human mind, but their scientific value can only be ascertained by comparing them with observational or experimental data derived from nature. Here, however, it is usually necessary to confine one's attention to a single habitat axis and to a single pair or small group of species in order to document relationships with adequate precision. In this way one can isolate and study such aspects of competition as root interactions[5] and the effects of environmental modifications on the equilibrium attained by species pairs[6]. With static organisms like plants, initial access to the resource is obviously of great significance, with the result that much emphasis has been placed upon the dispersal propagule and its establishment as a critical phase in plant interactions[7-10].

An alternative approach to the field study of coexistence is the manipulation of a habitat, either by disturbance, fertilization or selective species removal, and then observing the outcome on the balance of remaining species. This approach has proved particularly valuable in studying species interactions in intertidal communities[11-13], but it has also proved useful in studying community dynamics in terrestrial ecosystems, for example the fertilization experiments of Hurd *et al.*[14], and the use of natural badger disturbance by Platt and Weig[15] in their studies of opportunistic plant species in prairies.

There has been little attempt to date to develop a disturbance experiment within a plant community which will permit the testing of theoretical concepts of coexistence. Such an experiment is now reported by Silander and Antonovics in this issue of *Nature* (see p.557). They have altered the community composition of maritime plant communities by the selective removal of certain plant species from sample plots and observed the consequences for the remaining species. The effects are quantified in terms of a single response coefficient, C_{ij}, which compares the change in abundance (point cover or tiller number) of species *j* (following the removal of species *i*) with the

---

Peter D. Moore is in the Department of Plant Sciences, King's College London, 68 Half Moon Lane, London SE24 9JF.

original abundance of species *i*. The response coefficient will approach unity if species *j* expands to fill the entire space that was occupied by species *i* before its removal. Such a result would be suggestive of considerable niche overlap and hence high levels of competition for available resources, though caution is necessary in interpreting artificial removal responses.

The graphic representation of the results in their Fig.2 (see p.559) illustrates the complexity of interactions seen. For example, in the high salt marsh (*d*), the removal of *Spartina patens* (Gramineae) results in a marked increase in one species in particular, that is, *Fimbristylis* (Cyperaceae), and the reciprocal effect is shown by the experiment in which *Fimbristylis* is removed — *S. patens* expands strongly ($C = 0.693$). It is tempting to believe that these two species must normally be in acute competition. In the high marsh, *Fimbristylis* is the most abundant subsidiary species, but this is not the most influential factor determining the course of replacement, for if *S. patens* is removed from the low salt-marsh system, where *S. alterniflora* is the most abundant species, then it is still *Fimbristylis* which shows the greatest expansion, though its C value is far lower (0.072). This suggests that the overlap of resource utilization in these conditions is considerably less. *S. alterniflora*, in fact, is not altered by the removal of *S. patens*, indicating a lack of niche overlap, perhaps an example of perfect coexistence.

The authors are also able to identify 'diffuse' interactions in which the removal of one species results in similar responses from several of those remaining. This can be expressed numerically simply by using an evenness (equitability) index based on the Shannon diversity index. Such an occurrence is clearly indicated in their Fig.2 where *Muhlenbergia* is removed from the swale habitat (*c*), resulting in an almost equal expansion of all the remaining six species.

The potentialities of both the experimental method and the means of data expression are considerable. What is displayed here is a representation of plant community interactions in a form reminiscent of Hutchinsonian niche theory, though to interpret the coefficients precisely in this way would be stepping beyond the limits inherent in an approach which involves severe disturbance to community structure. The removal of one species produces a situation that is essentially artificial. The empirical method does, however, provide a valuable new way of approaching the vexed question of how plant species coexist. □

Lysosome proton pump identified

from Michael Geisow

IN 1893 Metchnikoff[1] used what must have been the earliest spectroscopic probe in living cells. He observed that litmus particles ingested by amoeba turned red and was able to conclude that the vacuoles of free-living phagocytes were acid. Now, nearly a century later, the same approach (modestly updated) has revealed that acidification of digestive vacuoles — secondary lysosomes — is achieved by proton-translocating ATPases. The recent paper by Ohkuma and his colleagues[2], reporting the latter result, also ends a decade of minor biochemical controversy.

Continuous enzymatic disassembly of macromolecules in secondary lysosomes releases new acid–base equivalents. To maintain the *p*H within the operating range of the hydrolases responsible (4.5–5.0), transport of basic equivalents out, or acidic equivalents in, must occur. The nature of the transport mechanism provided the subject of the controversy. Chief among the contenders for lysosomal *p*H control were proton-pumping ATPases and variants of the Gibbs–Donnan effect.

The issue was partially resolved by measurements of the ionic permeability of the lysosomal membrane[3,4]. In a Gibbs–Donnan equilibrium, impermeant macromolecules — acid hydrolases — in the lysosomes could buffer the content at a low *p*H given two assumptions. First, the isoelectric points of these proteins must lie in the range 4–5. Second, the membrane must be relatively permeable to H^+. On the latter point the hypothesis fell down, since the membrane turned out to have a relatively low permeability to H^+ and cations Na^+ and K^+ at physiological temperatures. This made the classical Donnan equilibrium unlikely but a clear proof of the proton-pumping alternative was lacking.

Further advance came with the development of an effective lysosomal *p*H meter — the fluorescent *p*H indicator dye fluorescein that can be used as a conjugate with dextran. Pinocytic activity conveniently delivers the conjugate to secondary lysosomes wherein *p*H can be monitored by emission spectroscopy. The *p*H of macrophage lysosomes was found to be 4.5–4.7 (ref. 5).

The biochemical exploitation of this intralysosomal *p*H probe required the problem of the isolation of lysosomes to be solved. Usually liver lysosomes are prepared by injection of the compound Triton WR-1339 in rats, to produce abnormally buoyant 'tritosomes', the difficulty then being whether the resulting pure organelles are representative. In the new work reported by Ohkuma, the *p*H probe was uniquely within lysosomes[6] so the presence of contaminating organelles was acceptable.

Ohkuma and his colleagues found that the *p*H of isolated liver lysosomes gradually increased in K^+-containing medium from an initial *p*H 5.0. The indication was not one of lysis, but more probably of slow cation permeation. The mitochondrial proton uncoupler FCCP and the K^+ ionophore valinomycin separately induced minor increases in *p*H, in agreement with limited lysosomal permeability to H^+ or K^+. Together these agents produced the expected collapse of *p*H in the isolated lysosomes. Mg^{2+}-ATP reduced the upward drift of lysosomal *p*H and the supply of a permeant anion (SCN^- or Cl^-) facilitated acidification, indicating that the *p*H-maintaining mechanism is electrogenic.

These symptons are diagnostic of a proton-translocating ATPase (H^+-ATPase). A series of inhibitors designed to characterize this enzyme showed that the lysosomal ATPase was unlike mitochondrial H^+-ATPase in being sensitive to quercetin, but unaffected by oligomycin. Ca^{2+} could not support ATPase activity, nor could ouabain [an inhibitor of (K^+ + Na^+)ATPase] suppress it. The K_m for ATP of the lysosomal proton pump is 0.1–0.2 mM, indicating that it should be working flat out at normal intracellular levels.

The closest analogy with the action of the lysosomal H^+-ATPase is provided in the secretion granules (catecholamine-containing) of the adrenal chromaffin cells. A granule H^+-ATPase is widely recognized. This enzyme acidifies the interior of the granule to *p*H 5.5 (refs 6, 7) and is also quercetin sensitive but unaffected by oligomycin[8]. The granule membrane is equally impermeable to

cations, but in this case, the high matrix concentration of weak acids (for example, nucleotides) more effectively buffers the *p*H than in the case of lysosomes. Hence the intragranular *p*H does not increase in the absence of ATP and is unaffected by external *p*H. Perhaps the two H^+-ATPases are identical since both derive from Golgi/endoplasmic reticulum.

The demonstration and partial characterization of the lysosomal H^+-ATPase will inevitably shift the focus of attention onto other cellular membranes where *p*H regulation may occur. Unfortunately, the present results cannot address the question of whether a *p*H-controlling mechanism is present in primary lysosomes or Golgi vesicles, since the delivery of the fluorescent conjugate is, by definition, to secondary lysosomes (endosome–lysosome fusion must have taken place). The method could, however, be used to measure the *p*H of endocytic vesicles which have not yet fused with lysosomes. The *p*H of phagocytic vacuoles has been considered to be reduced by a membrane NADPH oxidase; the *p*H of pinosomes is unclear. Do these organelles also possess proton pumps? ☐

The end of the message

from Nick Proudfoot

WITH the isolation and sequencing of eukaryotic genes now a standard, if sometimes tricky, procedure, attention is turning towards the question of how a eukaryotic gene works. Obviously, the first place to look at is the beginning of this process — transcriptional initiation and promoters — and much has already been achieved[1-3] with the discovery of CAT and TATA boxes. In the last year the focus on gene expression has shifted perceptibly '3'-wards'. Several studies have recently been reported on the transcriptional termination of eukaryotic RNA polymerase II (pol II) genes.

A picture now emerges of three different though related methods of mRNA 3'-end formation in eukaryotes. Histone genes generate their mRNA 3' ends by simply termination of transcription. This process involves the recognition of a specific termination sequence at the end of the mRNA. Yeast RNA polymerase II genes generate mRNA 3' ends by a coupled termination–polyadenylation process again apparently at a specific, although different, sequence. Finally, all other higher eukaryotic RNA polymerase II genes first terminate transcription, possibly at a specific sequence similar to the histone gene terminator. These mRNA precursors are then cut down close to an AAUAAA sequence and polyadenylated.

Early studies of mRNA sequence yielded the first clue to RNA polymerase II termination — several different mRNAs had the sequence AAUAAA about 15 base pairs from the 3'-terminal poly(A) sequence[4]. Since this was the only significant sequence homology close to the end of the mRNA, it was inferred that AAUAAA might constitute a recognition site for the enzymes involved in polyadenylation and/or pol II termination. Subsequently, this sequence was found at the 3' ends of all pol II genes (excluding histone genes and possibly all yeast genes) although in a few cases it varies by one base. In the case of histone genes, the mRNA produced is not polyadenylated, implying a link between the AAUAAA sequence and polyadenylation. However, the yeast genes that do not contain AAUAAA at their 3' ends do make polyadenylated mRNA.

The presence of AAUAAA at the end of viral mRNAs allowed the first direct tests of the sequence's function to be made. SV40 deletion mutants were constructed lacking the late gene AAUAAA sequence but containing the same sequence further downstream[5]. No wild-type 3' terminus was detected but rather polyadenylated 3' ends were formed 15 nucleotides away from the new AAUAAA sequence. These and similar experiments directly demonstrated the role of the sequence in positioning the poly(A) tail at the end of the mRNA[5]. Further complexities have followed for several different genes encode mRNAs with multiple 3' termini. First adenovirus[6], then dihydrofolate reductase[7] and immunoglobulin genes[8] were shown to have multiple 3' termini. In each mRNA, AAUAAA or a close homologue preceded the poly(A) tail by about 15 nucleotides. In some cases the selection of different 3' termini causes the expression of different gene products — secreted and membrane-bound forms of antibodies, for example[9].

An important advance in our understanding of these processes has recently come from Hofer and Darnell[10] at the Rockefeller University. They demonstrated the presence of RNA transcripts from the mouse β-globin gene that extended well beyond the 3' end of the mRNA sequence. Evidence that these 3'-extended transcripts were the precursors of mature mRNA was at first indirect but additional experiments that mapped the 3'-terminal position to a defined position 1,400 bases beyond the poly(A) addition site of the mouse β-globin gene have been described by Darnell at a recent conference*. Clearly the fact that these 3' extensions stop at a precise position suggests the transcripts are true globin mRNA precursors. In close agreement with these results, the primary transcripts of the DNA tumour viruses, adeno, SV40 and polyoma, have been unambiguously demonstrated to extend well beyond their poly(A) addition sites (see review, ref. 11). In polyoma, RNA transcripts have been found that are several times larger than the genome size, suggesting that RNA polymerase molecules transcribe in circles around the polyoma genome, never finding a terminator sequence that allows them to stop. These large transcripts must then be cut down to mRNA size by a specific endonuclease activity.

mRNA 3'-end formation thus appears to be a three-step process. First, RNA polymerase II terminates, at least in the case of mouse β-globin, at a defined sequence in the 3'-flanking region of the gene. Then an endonuclease cleaves this primary transcript down to 15 bases 3' to the AAUAAA sequence. Finally, this newly formed 3' end is polyadenylated. It seems plausible to suggest that both the RNA endonuclease and poly(A) polymerase activities recognize the same ubiquitous AAUAAA sequence.

A significantly different approach is revealed in the H2A histone gene of sea urchin[12]. Histone mRNA, although synthesized by RNA polymerase II, is not polyadenylated and does not possess the 3' AAUAAA sequence present in other mRNAs. However, a 23 base pair sequence, including an imperfect inverted repeat at the 3' end of the histone mRNA, is essential for 3'-end formation. When specific deletions of this sequence were constructed and the mutant genes injected into oocyte nuclei the resulting RNA transcripts were larger than histone mRNA and heterogeneous in size, due to multiple 3' termini in the 3'-flanking region or spacer sequence of the histone gene. It seems likely that the 23 base pair inverted repeat sequence is a termination signal for RNA polymerase II. Possibly the inverted repeat forms a secondary structure in the nascent RNA transcript that is recognized by pol II termination factors. Formally, it is still possible that extended 3' termini are

0028-0836/82/310516-02$01.00

cleaved down to the mRNA 3′ terminus. However, no evidence for such extended 3′ termini in the normal gene has been obtained, unlike poly(A)-containing mRNAs. The histone genes may have a similar termination mechanism to other pol II genes, but simply miss out the additional endonucleolytic and polyadenylation steps — presumably due to the absence of a suitably positioned AAUAAA sequence. Such a theory seems more plausible given that the same RNA polymerase enzyme transcribes both types of gene. This model will soon be put to the test when the true termination sites of several different pol II genes (that encode poly(A) containing mRNAs) are mapped and sequenced. These genes may possess a sequence identical or similar to the histone termination signal. Unfortunately, most gene sequence studies extend only a few hundred base pairs beyond the poly(A) site. If termination occurs over 1 kb 3′ to the poly(A) site, as appears to be the case with mouse β-globin, then possible termination signals will not yet have been sequenced.

Yeast pol II genes provide yet another variation. Recent studies on a naturally occurring mutant of the yeast Iso-1-cytochrome *c* gene reveal transcripts that are much longer than in wild-type yeast, due to extended 3′ termini[13]. Detailed structural analysis reveals that the mutant gene contains a 38 base pair deletion at the 3′ end of the mRNA sequence. Sequence comparison of all characterized yeast pol II genes shows that the deleted region includes a sequence homology present in all the yeast genes but different from AAUAAA. Curiously, in this mutant all the 3′-extended RNA transcripts are polyadenylated as is the wild-type mRNA. This lack of specificity as to which 3′ end is adenylated is clearly different from the situation in higher eukaryotes. Presumably termination and polyadenylation are coupled events, so that only pol II transcripts end with poly(A) tails. It would appear that yeast pol II genes are intermediate between higher eukaryotic histone genes and other pol II genes encoding poly(A)-containing mRNAs. ☐

Two different viral transforming proteins bind the same host tumour antigen

from David Lane and Ed Harlow

A RECENT publication[1] by Sarnow and his colleagues shows that in adenovirus-transformed mouse cells, a host protein, p53, becomes tightly associated with a 58,000-molecular weight product of the adenovirus E1b region — one of the regions whose product is responsible for the transforming capability of adenovirus. What makes the finding of particular interest is that in SV40-transformed mouse cells, p53 also binds to the SV40-coded large T antigen[2,3], expression of which is thought sufficient to transform rodent cells. That proteins from unrelated DNA tumour viruses should both form a stable highly specific complex with p53 (ref. 4) immediately suggests the possibility of a common function in transformed cells for either the viral proteins or the complexes themselves.

Interest in p53 has not come solely from tumour virology, but also from the discovery of antibodies to p53 in sera from animals with a wide variety of tumours. Anti-p53 antibodies were first detected almost simultaneously in two separate fields. DeLeo and co-workers reported that a proportion of sera from mice with methylcholanthrene-induced tumours had anti-p53 antibodies[5] while workers with SV40 reported that p53 could be immunoprecipitated with sera from animals with tumours of SV40-transformed cells[2,3]. Subsequently, anti-p53 antibodies were found in mice with Abelson-induced leukaemia[6]. Why this host protein should become immunogenic in these animals is not clear but the presence of anti-p53 antibodies in tumour sera is not restricted to experimental animals. About 10 per cent of sera from human breast cancer patients also contain anti-p53 activity, while no activity against p53 can be detected in sera from normal patients[7].

It is commonly said that the level of p53 is higher in transformed cells than in normal cells[5,8,9]. Levels of p53 clearly increase following SV40 transformation, probably because of stabilization by binding to large T antigen: in mouse 3T3 cells, p53 has a half life of approximately 20 min which increases to more than 24 h in SV40-transformed 3T3 cells[10].

A similar set of observations might now be expected in adenovirus-transformed cells. Reports of metabolic labelling and immunoprecipitation experiments on a wide variety of non-SV40-transformed cells have suggested that they have higher levels of p53 than their non-transformed counterparts. Increased levels of p53 labelling have also been reported to follow lectin stimulation of lymphocytes[11] and to be associated with explants of early embryos[12].

These reports are consistent with the hypothesis that increased levels of p53 accompany transformation or rapid cell growth but it must be remembered that the incorporation of radiolabelled precursors into immunoprecipitated p53 may not be an accurate measure of the total protein levels of p53. For example, as judged by radiolabelled p53, SV40-transformed mouse cells have two to three times more p53 than mouse F9 teratocarcinoma cells, but when tested in a radioimmunoassay for total protein, F9 cells have approximately 50-fold less p53 than the SV40-transformed cells[13]. Until an accurate assay for total cold p53 is widely used, the claim that elevated levels of p53 frequently accompany transformation will have to be held in some doubt.

Although the ability to label p53 may be reduced in normal cells, careful examination has shown that p53 can be found in almost all cell cultures. The only known exceptions to this rule are the human tumour cell lines HeLa and EJ[9]. No detectable levels of p53 have been found in these cells, and if these negative data prove correct, p53 cannot be essential for cell viability. Likewise, p53 does not represent a universal marker for transformation as it is present in normal cells and absent from some transformed cells.

Although there are very few clues to understanding the role of p53 in normal or transformed cells, knowing what viral processes are dependent or altered on binding to p53 is probably one of the best avenues to determining its function. The fact that two DNA tumour viruses both produce proteins that complex p53 should greatly aid this search and may provide a clue to the immunogenicity of p53 in animals with cancer. ☐

The beginnings of solar-terrestrial studies

from David W. Hughes

THE early years of the nineteenth century mark a watershed in astronomy. From that time astronomers ceased to concentrate on recording the positions and movement of celestial objects and astrophysics began its growth into the dominant force it is today. As documented in a recent review of the birth of the study of solar-terrestrial relations (*Vistas Astr.* **25**, 419; 1982), a factor that helped this transformation was the realization, as a result of geomagnetic, auroral and meteorological observations, that there was an obvious non-gravitational interaction between the Sun and the Earth.

Our knowledge of the existence of sunspots is centuries old but the periodicity of their occurrence, the so-called solar cycle, was only reported as recently as 1843. H. Schwabe, a one-time apothecary of Dessau, devoted himself to the observation and recording of sunspots (some say partly in the hope of discovering an intra-Mercurial planet). By 1838 he began to suspect that the 'spottiness' of the Sun changed with a period of about 10 years. He published his conclusions in *Astronomische Nachrichten* (**20**, no. 495) but his discovery did not become widely known until Baron von Humboldt publicized it in 1851 in the third volume of his popular work *Cosmos*. This popularization opened the flood gates.

Colonel Sabine of the British army had been analysing a series of magnetic field measurements taken from a group of observatories dotted throughout the British colonies. They showed that the Earth's field underwent small fluctuations, the amplitudes of which varied with time. As Sabine wrote: "It happens by a most curious coincidence" that the magnitude and frequency of magnetic disturbances, on a global scale, had a maximum in 1848 and a minimum in 1843, following the sunspots. Sabine published his findings in March 1852 and A. Gautier and Rudolf Wolf independently came to the same conclusions and published in the same year.

As far back as 1747, Hiorter queried

> "Who could have thought that the northern lights would have a connection and a sympathy with the magnet, and that these northern lights, when they draw southwards across our zenith or descend unequally towards the eastern and western horizons could, within a few minutes, cause considerable oscillations of the magnetic needle through whole degrees?"

Suggestions of a close link between solar cycle and the frequency of aurorae were quickly made in the 1850s but, unfortunately, the scarcity of records made the periodicity of the auroral occurrence frequency difficult to establish.

Speculation about a connection between spots and aurorae and spots and the weather had been made in the mid-eighteenth century. In 1801, William Herschel wen so far as to try and find a correlation between the number of spots and the price of corn, the latter obviously being influenced by the amount of fine weather. The 1850s was a time when all regularly observed meteorological variables were analysed for periodicities. The British with their colonial interests were especially involved and Indian weather reports were carefully perused with the hope of producing reliable long-range weather predictions.

The relationship between solar cycles and variations in magnetic activity was confirmed when scientists realized that predictions of magnetic disturbances made by using sunspot observation were reasonably good. Astrophysical mechanisms connecting changes on the Sun and the consequent particle and radiation flux to aurorae and magnetic disturbances on Earth were also speedily established. The importance of the solar cycle was recognized and John Herschel's question "What can there be to determine a periodicity of this kind in the Sun?" became, and still remains, an important stimulus to astrophysicists.

Sun–weather relationships were a different matter. *Post hoc* correlations might be detected but predictions from them lacked accuracy. There were also far too many weather parameters to choose from. Even today, though many causal relationships have been suggested between ground temperature, rainfall, pressure and storms and sunspot activity, none has been generally accepted. □

David W. Hughes is a lecturer in Astronomy and Physics at the University of Sheffield, Sheffield S3 7RH.

Air pollution in the Arctic

from B. Ottar

AN extensive study of pollutant transport and deposition in the Arctic has recently been begun by the Norwegian Institute for Air Research with the support of British Petroleum Ltd. Not only is the Arctic an important region climatologically, but the increasing interest in the exploitation of Arctic oil reserves makes it important to obtain baseline pollutant measurements as soon as possible.

Transport of air pollutants into the Arctic has received much attention recently, and it seems that the Arctic haze north of Barrow, first reported in 1956, is due to large-scale transport of polluted air masses. Aerosol samples from the Arctic show that the concentrations of trace elements associated with fossil fuel combustion reach a pronounced maximum in February–March (K.A. Rahn & R.J.M. Caffrey *Proc. WMO Symp. on Long-Range Transport of Pollutants,* Sofia, 25, WMO no.538; 1979). During summer, aerosol concentrations are very low (H. Lannefors, J. Herntzenberg & H.C. Hansson *Tellus* **34**A, no.1; in the press). This extreme variation is explained by the formation of a cold high-pressure centre over northern USSR and Siberia in winter, which forces the Atlantic westerlies northwards into the Barents Sea. This enhances the south to north advection associated with the low pressures in the Atlantic and the Norwegian Sea. In addition, pollutant transformation and deposition rates are very low in the cold and dark winter season. Polluted air masses from Europe and the USSR are transferred into the polar basin and across the North Pole towards northern Alaska and Canada. In summer, the circulation becomes more circumpolar, and dry deposition and precipitation prevent anthropogenic aerosols from reaching the high Arctic.

The new study includes an expansion of the present Norwegian measurement programme. Four ground stations in the high Arctic (Bear Island, Hopen, Spitsbergen, Jan Mayen) and two stations along the Norwegian coast will operate over a three year period, starting summer 1982, together with two inland stations. At all stations sulphur dioxide, sulphate aerosol and precipitation will be monitored throughout the year. More extensive supplementary measurements, including high-volume sampling and chemical analysis of aerosols and hydrocarbons, will be made during a few 1–2 month periods each year. In the same periods, intensive aerosol measurements will be carried out by aircraft and the vertical and horizontal extent of the polluted air masses mapped. Soil samples as well as biological samples will be collected to evaluate the deposition and accumulation of trace elements and organic components. In particular, the accumulation of chlorinated hydrocarbons, whose presence in the Arctic air has been demonstrated, will be examined in fish from isolated lakes.

Turbulent dispersion over ocean surfaces will also be studied in order to provide a better basis for calculation of hazard zones in connection with blow-outs and other accidents. Such studies and the background air pollution inventory will help the Norwegian Government evaluate possible damage from Arctic oil activities.

B. Ottar is Director of the Norwegian Institute for Air Research, PO Box 130, 2001 Lillestrom.

ARTICLES

Nd, Sr and Pb isotopic systematics in a three-component mantle: a new perspective

Alan Zindler[*], **Emil Jagoutz**[†] **& Steven Goldstein**[*]

[*] Lamont-Doherty Geological Observatory and Department of Geological Sciences, Columbia University, Palisades, New York 10964, USA
[†] Max Planck Institut für Chemie, Saarstrasse 23, Mainz, FRG

Average Nd, Sr and Pb isotopic compositions for oceanic basalts indicate that the present day mantle consists of three chemically independent components. The recognition of a third mantle component obviates geochemical arguments which have been used to support chemical stratification and convective decoupling within the mantle, and the transport of lead to the core throughout geological time.

RECENT geochemical modelling of mantle differentiation and crustal growth[1-5] has suggested that Nd and Sr isotopic variations in young mantle-derived rocks may be explained by mixing of two mantle components, 'MORB-type' or 'depleted mantle' material and 'undifferentiated' or 'slightly enriched' mantle material. In this context, apparently enigmatic variations in Pb isotope ratios have been interpreted as indicating that the U–Th–Pb system has suffered a more complex evolution in the earth than either Sm–Nd or Rb–Sr. An alternative interpretation of the data has been proposed by Zindler and Jagoutz[6,7] who suggested that variations in Nd, Sr and Pb isotopic compositions of mantle-derived rocks indicate the existence of at least three chemically independent mantle components. The acquisition of Nd isotope data from St Helena (ref. 8 and Lamont unpublished data) was particularly important to the formulation of this hypothesis because it showed that St Helena, which is characterized by the highest $^{206}Pb/^{204}Pb$ ratios ever measured in young basalts (see Fig. 1*d*), falls below the 'mantle array' in a plot of $^{143}Nd/^{144}Nd$ against $^{87}Sr/^{86}Sr$ (see Fig. 1*a*).

The term 'component' is used so as not to imply the connotations of a word like 'reservoir', that a physical entity with these compositions actually exists in the mantle. We also do not mean to imply that only three isotopically distinct materials exist within the mantle (a brief look at the crust should dispel any such notion). However, the data indicate that, while any number of isotopically distinct materials may exist, they may all be described as linear combinations of three components.

The first-order difference between the two- and three-component models is not simply the number of mantle components invoked, for any subdivision of the mantle into two, three or *n* components is necessarily a simplification of the real situation. The basic difference lies in the nature of the mechanisms which must be called on to explain the differentiation of the mantle into its major observable components. Processes which involve the mobilization of silicate liquids or silica-rich fluids within the mantle are thought to fractionate parents from daughters in each of the isotope systems under consideration. Therefore, to propose that, in a gross sense, Nd and Sr isotopic variations may be explained by two mantle components while

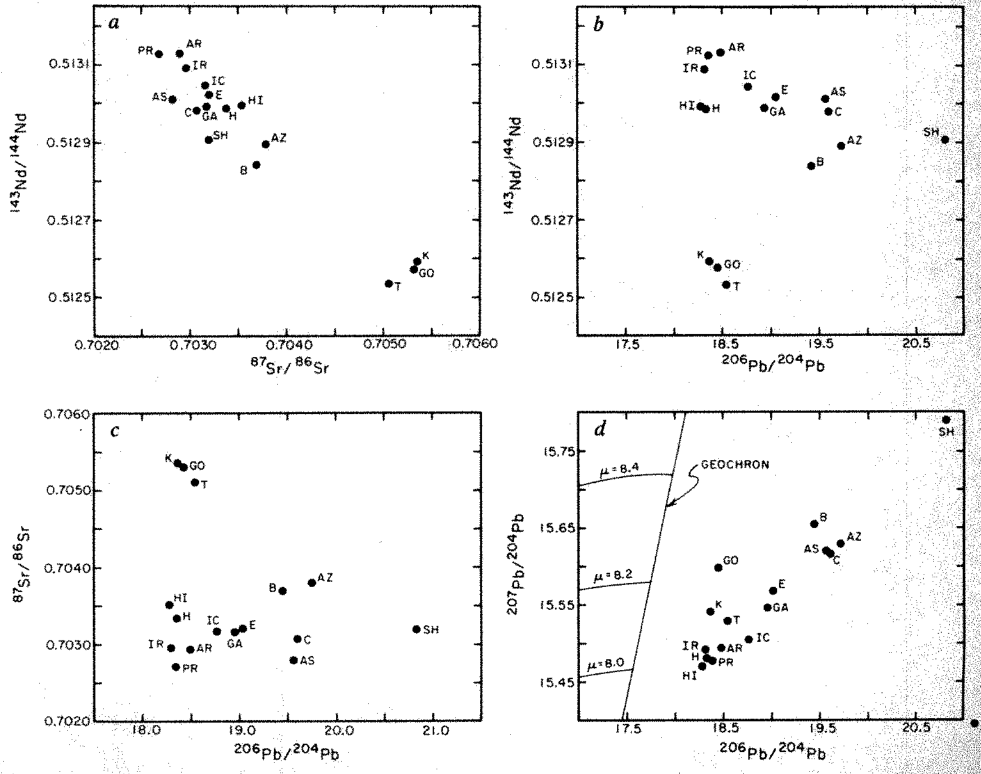

Fig. 1 Two-dimensional variation diagrams for average values of Pb, Nd and Sr isotopes in basalts from ocean islands and ridges. Localities are labelled as in Table 1. *a*, $^{143}Nd/^{144}Nd$ versus $^{87}Sr/^{86}Sr$; *b*, $^{143}Nd/^{144}Nd$ versus $^{206}Pb/^{204}Pb$; *c*, $^{87}Sr/^{86}Sr$ versus $^{206}Pb/^{204}Pb$, *d*, $^{207}Pb/^{204}Pb$ versus $^{206}Pb/^{204}Pb$.

0028–0836/82/310519—05$01.00

three or more components are required by Pb isotope variations is to imply that some geochemically active mantle process causes severe fractionations of U and Th from Pb without significantly affecting Rb/Sr and Sm/Nd ratios, and furthermore, that this process is not one governed solely by solid–liquid–fluid equilibria in a silicate system. Based on this kind of reasoning, several authors[9–11] have proposed that Pb has been transferred from the mantle to the core in a sulphide phase throughout geological time, causing a progressive increase in mantle U/Pb and Th/Pb ratios. Because the other elements under consideration are not chalcophile in nature, their relative abundances in the mantle will not have been affected by this process. In contrast, if Nd, Sr and Pb isotopic variations support the existence of more than two mantle components, then fractionations of all three parent–daughter systems may conceivably be in response to magmatic or metasomatic processes operating within the mantle without calling on a special process to fractionate U and Th from Pb.

We now examine mantle Nd, Sr and Pb isotopic variations in multi-dimensional space to investigate systematics which may be obscured in two-dimensional variation diagrams. In three, four or five dimensions, average isotopic compositions for individual ocean islands or island groups and mid-ocean ridges define a planar array with a high degree of precision and indicate that mantle isotopic variations are best described by mixing between three chemically independent mantle components. These results suggest that: (1) processes which involve the mobilization of silicate liquids or silica-rich fluids within the mantle, such as metasomatism of magma generation, can account for differentiation of the three isotope systems without calling on a special process to produce apparently complex Pb isotope variations; (2) mixing between mantle components must occur without significant fractionation of daughter element ratios (Sr/Nd, Sr/Pb and Nd/Pb); (3) mass-balance arguments which have been used to support convective isolation of the lower mantle[2–4] (and the resulting chemical stratification of the mantle) are not valid, due to the positive identification of an additional important mantle component; and (4) the 'bulk Earth' $^{87}Sr/^{86}Sr$ ratio is about 0.7052, significantly higher than the range of previous estimates (0.7045–0.7050)[12–14].

Recognition of these systematics in the mantle places strong constraints on the evolution of the continental crust. The continental crust is not constrained to lie on the 'mantle plane' of compositions. However, given that the continental crust has been derived from the mantle through time (albeit indirectly), the average continental crust must lie close to the plane, within a restricted range of compositions. Details of continental crust evolution, in the context of those mantle systematics, will be discussed elsewhere[15,16].

Results and discussion

Investigation of the large-scale chemical structure of the mantle is facilitated by averaging the small-scale isotopic heterogeneities known to exist in the mantle beneath specific volcanic centres (such as the Reykjanes Peninsula[17]). In other words, we would like to obtain representative isotope ratios for mantle segments which are large when compared with the scale of melting. In light of these considerations, we have calculated average Nd, Sr and Pb isotope ratios for individual islands, island groups and mid-ocean spreading centres. (This method was previously used[18] to examine Rb–Sr systematics in the sub-oceanic mantle.) Because we are attempting to evaluate mixing relationships between mantle components, the desired information will not be obscured by the enhanced or diminished representation of one or more components at a given locality.

The current data base is only marginally sufficient to accomplish this task with some statistical credibility, due to a lack of single samples for which there are Nd, Sr and Pb isotopic analyses. Hence, we included all available high-precision analyses of oceanic basalts for each isotope system. This typically results in average Pb isotope ratios which are based on analyses of different samples from those used to obtain the average Nd and Sr isotope ratios. Although the approach is not ideal, it is necessitated by the nature of available data. Had we been restricted to dealing only with those samples for which Nd, Sr and Pb isotopic analyses exist, the data base would simply not have been sufficient to perform the multidimensional analysis presented here.

Average Nd, Sr and Pb isotope ratios for various localities are reported in Table 1. Also shown are the number of samples used for computation and the sources for the data. The data set used to calculate these averages has been significantly augmented by the inclusion of unpublished analyses done at Lamont and by White. The average values are plotted using standard representations in Fig. 1. While the averaging tends to reduce noise, the patterns formed by the data in these diagrams are familiar from the literature. One should note that in Fig. 1*a*, the $^{143}Nd/^{144}Nd$ versus $^{87}Sr/^{86}Sr$ diagram, the data do form a convincingly linear array.

Planes have been fitted to the 10 possible combinations of 3 of the 5 isotope ratios using a standard multiple linear regression treatment. For 5 of the 10 combinations, the correlation coefficient, r, is >0.98; for other combinations, r can go as low as 0.72. Factor analysis techniques have been used to evaluate simultaneously the data in five dimensions ($^{143}Nd/^{144}Nd$, $^{87}Sr/^{86}Sr$, $^{206}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$, and $^{208}Pb/^{204}Pb$). Using an autoscaling technique[47], in which the data within each isotope system are normalized to the total variation within that system,

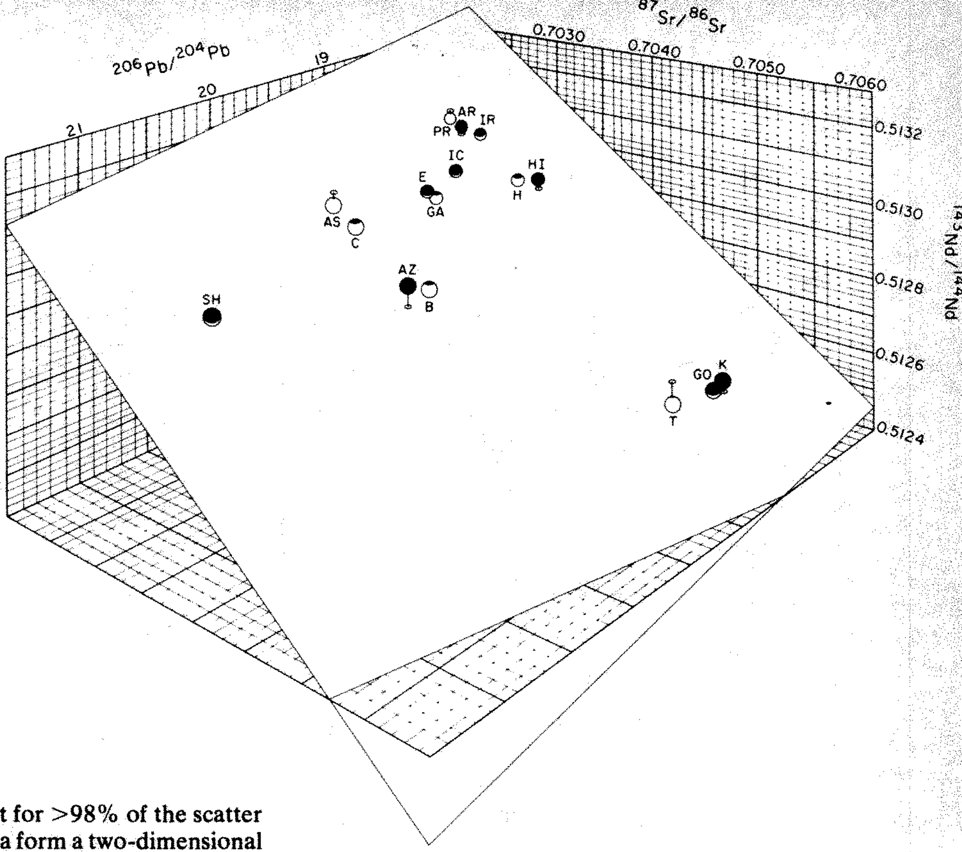

Fig. 2 Three-dimensional plot of average $^{206}Pb/^{204}Pb$, $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ for basalts from ocean islands and ridges. The best-fit plane is shown. Closed and open symbols lie above and below the 'mantle plane', respectively. Lines connecting data points to the plane are parallel to the $^{143}Nd/^{144}Nd$ axis and indicate those points which do not intersect the plane. Localities are labelled as in Table 1.

two vectors in five dimensions account for >98% of the scatter in the data, demonstrating that the data form a two-dimensional or planar array. The plane formed by these two vectors is not normal to the plane formed by the Nd and Sr axes. A complete treatment of results for the five isotope systems will be published elsewhere[15]. Only the results for $^{143}Nd/^{144}Nd$ versus $^{87}Sr/^{86}Sr$ versus $^{206}Pb/^{204}Pb$ will be discussed in detail here.

The plane fit to the data for $^{143}Nd/^{144}Nd$, $^{87}Sr/^{86}Sr$ and $^{206}Pb/^{204}Pb$ has a correlation coefficient of 0.984, is given by the equation

$$-0.334640(^{87}Sr/^{86}Sr)-1.48742(^{143}Nd/^{144}Nd)$$

$$-8.59379\times10^{-5}(^{206}Pb/^{204}Pb)+1=0$$

and is shown in Fig. 2. The small magnitude of the coefficient for $^{206}Pb/^{204}Pb$ results in part from the large magnitude of $^{206}Pb/^{204}Pb$ ratios compared with $^{87}Sr/^{86}Sr$ and $^{143}Nd/^{144}Nd$ ratios. The tie lines between the data points and the plane are drawn parallel to the $^{143}Nd/^{144}Nd$ direction and are meant to aid three-dimensional visualization. The fit of the data to the plane is extremely good. Deviations taken normal to the plane are smaller than experimental errors for $^{87}Sr/^{86}Sr$ and $^{206}Pb/^{204}Pb$ and average only slightly in excess of typical experimental errors for $^{143}Nd/^{144}Nd$.

While the fit of the data to the plane cannot be contested, one may wonder whether some special differentiation process has affected the U–Pb system, especially in light of the apparently linear correlation of $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ seen in Fig. 1*a*. In other words, it may be conceivable to have only two chemically independent components for $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$, and three for $^{206}Pb/^{204}Pb$. If three components are appropriate for all three isotope systems, a two-dimensional projection taken parallel to the plane should yield an array which is significantly more linear than that seen in Fig. 1*a*. We have tested this by rotating the plane about the $^{87}Sr/^{86}Sr$ axis. The resulting diagram (Fig. 3) is a plot of $^{87}Sr/^{86}Sr$ versus a function of $^{143}Nd/^{144}Nd$ and $^{206}Pb/^{204}Pb$. Compared with Fig. 1*a*, many data points have been rotated into the trace of the plane in Fig. 3, resulting in a significantly improved linear correlation. Deviations from the trace of the plane in Fig. 3, parallel to the $^{87}Sr/^{86}Sr$ axis, average a factor of two smaller than those deviations from a best-fit line to the data in Fig. 1*a*. Thus, it becomes clear that, as suspected, there is important information contained in the scatter of data about the 'mantle array' in Fig. 1*a*. We consider that this critical test of the proposed three-component model has been passed.

Chemically independent mantle components are produced through differentiation of a mantle which is well-mixed subsequent to core formation. Differentiation of the mantle in response to magmatic processes, such as basalt generation or the extraction of continental crust, will cause fractionation of Sm/Nd, Rb/Sr and U/Pb ratios. Resulting mantle components will have distinct Nd, Sr and Pb isotope ratios. Models which have been proposed to explain Nd and Sr isotopic variations in oceanic basalts have generally called on two chemically distinct mantle components[1–5]. However, several authors[1,5,10–12,19,20] have noted that simple mixing of two components is not sufficient to explain Pb isotopic variations (see Fig. 1). To resolve this apparent dilemma, a process must be identified which fractionates U from Pb, but not Sm from Nd, nor Rb from Sr, thus affecting only Pb isotope systematics. The transport of Pb to the core throughout geological time has been proposed[1,9–11] as such a mechanism. Having recognized the coherence of Nd, Sr and Pb isotope systematics in the mantle, such *ad hoc* proposals may no longer be necessary. For the elements of interest then, we consider the mantle and crust to be a closed system. Subsequently, 'bulk Earth' shall refer only to the mantle–crust system and exclude the core. In this context, the 'bulk Earth' Pb isotopic composition must lie on the Pb–Pb geochron.

In the context of this three-component model for the mantle, we are able to make a new and more accurate estimate of $^{87}Sr/^{86}Sr$ in the 'bulk Earth'. Previous estimates average about 0.7047 (refs 12–14) and are made using only the $^{143}Nd/^{144}Nd$ versus $^{87}Sr/^{86}Sr$ correlation together with the chondritic value of $^{143}Nd/^{144}Nd$ (most recently and accurately determined by Jacobsen and Wasserburg[21]). By using the equation given for the 'mantle plane', a 'bulk-Earth' $^{206}Pb/^{204}Pb$ ratio of 17.767 (corresponding to a present-day μ equal to 8.2, an age for the Earth of 4,570 Myr and initial Pb isotopic compositions from

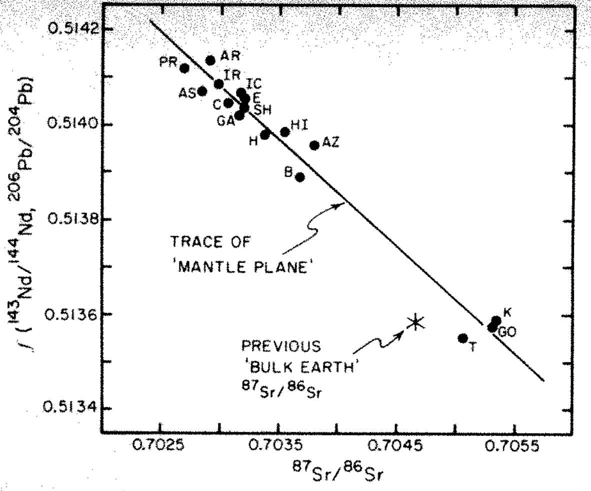

Fig. 3 Two-dimensional projection, taken parallel to the 'mantle plane', of average $^{206}Pb/^{204}Pb$, $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ values for basalts fron ocean islands and ridges. The coordinate system has been rotated about the $^{87}Sr/^{86}Sr$ axis so that the 'mantle plane' is normal to the page. The abcissa is $^{87}Sr/^{86}Sr$; the ordinate is a function of both $^{206}Pb/^{204}Pb$ and $^{143}Nd/^{144}Nd$ given by:

$$f(^{143}Nd/^{144}Nd,\ ^{206}Pb/^{204}Pb)$$
$$=[(^{143}Nd/^{144}Nd)^2+(^{206}Pb/^{204}Pb)^2]^{1/2}$$
$$\times[\sin[\arctan((^{143}Nd/^{144}Nd)/(^{206}Pb/^{204}Pb))+0.0031035]]$$

Localities are labelled as in Table 1. Note that this projection yields a significant decrease in scatter compared with Fig. 1*a*. The trace of the 'mantle plane' is shown for reference. The previous 'bulk Earth' estimate for $^{87}Sr/^{86}Sr$ of 0.7047 is shown to lie farther from the 'mantle plane' than any single data point, when plotted assuming 'bulk Earth' $^{143}Nd/^{144}Nd = 0.51262$ and $^{206}Pb/^{204}Pb = 17.767$ (corresponding to a present day $\mu = 8.2$, an age for the Earth of 4,570 Myr, and initial Pb isotopic compositions from Tatsumoto *et al.*[22]). A 'bulk Earth' estimate of $^{87}Sr/^{86}Sr = 0.7052$ is compatible with both the 'mantle plane' and reasonable values for 'bulk Earth' Nd and Pb isotope ratios.

ref. 22), and the chondritic $^{143}Nd/^{144}Nd$ value of 0.51262, we have estimated a 'bulk-Earth' $^{87}Sr/^{86}Sr$ ratio of 0.7052. (While a μ of 8.2 is considerably higher than μ values observed in Cl chondrites, it is less than μ values observed in some differentiated meteorites. If lead is treated as a volatile element, its depletion in the Earth, relative to Cl chondrites, is not inconsistent with depletions observed for other volatile elements.) An $^{87}Sr/^{86}Sr$ ratio of 0.7047 would imply a $^{206}Pb/^{204}Pb$ ratio of about 20 in the 'bulk Earth', clearly too high for any reasonable 'bulk Earth' μ value. The new value of 0.7052 for the 'bulk Earth' $^{87}Sr/^{86}Sr$ ratio implies a Rb/Sr ratio of 0.032. Also, when compared with the $^{230}Th/^{232}Th$ versus $^{87}Sr/^{86}Sr$ correlation of Condomines *et al.*[23], an $^{87}Sr/^{86}Sr$ ratio of 0.7052 yields a $^{232}Th/^{238}U$ ratio of about 3.9 in the 'bulk Earth'. This is compatible with Tatsumoto's[19] estimate that the 'bulk-Earth' κ value lies between 3.8 and 4.0.

The fit of the data points to a plane carries implications for the relative compositions of the three components, since mixing relationships are not planar in the general case. A planar mixing surface, rather than a curved surface or a cloud, will only result when the three components have Sr/Nd, Sr/Pb and Nd/Pb ratios which are not too dissimilar, and when the mixing process does not produce severe fractionations of these ratios. That such a planar array is observed offers some insight into mantle dynamics.

Examples from the literature document mantle metasomatism on a small scale[24,25] or call on mantle metasomatism as a precursor to melt generation in the mantle[17,24]. The present results suggest that metasomatic processes, which fractionate both parent/daughter ratios and daughter/daughter ratios, do not have an important role in determining the gross chemical characteristics of the mantle. The planar array is most easily understood if mixing between components in the mantle occurs in the solid state. However, the constancy of Sr/Nd in volcanic rocks[26] indicates that a planar array will result from mixing of magmas where Sr/Pb and Nd/Pb ratios are not fractionated by magma generation processes. At present, our knowledge of solid/liquid partitioning for Pb is not sufficient to resolve this point[19].

Source materials for magmas in the mantle may then be considered as composite mixtures of varying amounts of the three components without requiring chemical stratification within the mantle. This is a realistic scenario in which to produce the chemical and isotopic variations observed at individual volcanic centres[27]. In some areas, however, where metasomatism has affected the source mantle before basalt generation, isotopic compositions of basalts are expected to deviate from the 'mantle plane'.

Recent models[2–4] have proposed that the continental crust is the only geochemical complement to the depleted mantle observed at mid-ocean ridges. In such a context, material balance arguments have been used to show that only 20–50% of the mass of the mantle need be depleted to produce the continental crust. These arguments have been taken to support convective decoupling of the upper and lower mantle, and consequently, chemical stratification of the mantle. Having identified a third mantle component, we can no longer realistically consider that continental crust is the sole complement to the depleted mantle. (This was pointed out by Anderson[5] using arguments based on the presence of an enriched reservoir in the mantle). Therefore, the material balance arguments used previously are invalid, and from a geochemical standpoint the question of whole-mantle versus part-mantle convection remains open. This point has been made independently by Allegre *et al.*[28] who show that uncertainties in input parameters are sufficient to allow the possibility that the whole mantle has been depleted to produce the continental crust, even in the context of a two component mantle.

Nd, Sr and Pb isotope ratios have been shown to delineate three chemically distinct components within the Earth's mantle. Two of these components, undifferentiated or slightly enriched mantle material, and MORB-type or depleted mantle material, have received much attention recently[2,3,12,5,29]. On independent grounds, Hofmann and White[30–32], Chase[33], and Zindler and Jagoutz[6,7], have suggested that recycled oceanic crust may have a role in determining the chemical characteristics of volcanics at some ocean islands. Therefore, it is appropriate to consider whether subducted ocean crust will have the chemical characteristics required by the third component (high U/Pb and Th/Pb, low Th/U, and intermediate Sm/Nd and Rb/Sr ratios with respect to the other components). The chemical characteristics of subducted ocean crust are determined by magma generation processes at mid-ocean ridges and volcanic arcs, by sea-floor alteration processes, and by the presence of seamounts or ocean islands. The effects of these processes on Rb/Sr and Sm/Nd can be predicted on the basis of the geochemical behaviour of these elements. However, the behaviour of U and Pb during magma generation and ocean crust alteration is complex and poorly understood [19,34]. Further, a range of isotopic compositions will result from the subduction of ocean crust materials at different times during Earth history. An accurate assessment of the suitability of subducted ocean crust for the third component must await further work.

Summary and conclusions

Nd, Sr and Pb isotope ratios in mantle-derived rocks define a plane in three, four or five dimensions, and demonstrate that the interactive portion of the Earth's mantle is composed of three chemically distinct and independent components. The recognition of a third significant chemical component in the mantle obviates geochemical arguments which have been used to support chemical stratification and convective decoupling within the mantle, and the transport of Pb to the core throughout geological time.

We anticipate that the 'mantle plane' will be useful as an aid in understanding geochemical aspects of petrogenetic processes in different tectonic settings. As discussed above, specific conditions of mixing are required to generate magmas whose isotopic compositions lie on the plane. Where isotope ratios in volcanic products are observed to deviate significantly from the plane, constraints on the nature of magma generation processes and source materials can be inferred. For example, melting of metasomatically veined mantle may produce magmas with anomalous isotopic compositions. In addition, products of intracrustal differentiation are not constrained by mantle isotope systematics and may have isotopic compositions which lie far off the mantle plane. Where crustal materials are involved in igneous processes at volcanic arcs or sites of intra-continental volcanism, the isotopic compositions of resulting magmas are expected to lie off the plane.

We thank Stan Hart for encouragement and for a helpful review of an early version of this manuscript. Previously unpublished data supplied to us by Bill White were greatly appreciated. We thank Gerd Brey, Christa Goepel, Brendon Griffith and Bill White for a helpful evening of discussion, Claude Allegre, Don Anderson and Al Hofmann for constructive reviews and Dave Zindler and Patty Catanzaro for the graphics. Geological, diatom, pollen and archaeological studies, supported by 24 original radiocarbon dates, provide new evidence to illustrate the Holocene history of Lake Turkana, Kenya. High and intermediate lake levels are recorded between 10,000 and about 3,000 yr BP, *with a general regression during the later Holocene. Archaeological finds document the transition from a fishing-based economy to pastoralism.*

DURING the past 15 yr, considerable evidence has been presented to illustrate the Holocene limnological histories of many East African lakes[1-6]. Research has demonstrated several former periods when lake levels were higher than today, some of which were broadly synchronous in different basins, and which have generally been attributed to palaeoclimatic variations. We report here the principal results of a multidisciplinary study of the Holocene sediments of Lake Turkana, providing new evidence for lake level fluctuations, and for the palaeoclimatology, palaeoecology and archaeology of East Africa.

Lake Turkana, one of the oldest and largest African lakes (7,500 km^2, 125 m maximum depth), occupies a predominantly semi-arid basin of internal drainage at the northern end of the Kenya Rift (Fig. 1). Its waters, which are moderately saline and alkaline[7-10], are mostly derived from the Ethiopian Highlands, through the Omo River[11]. Like most non-outlet lakes, Turkana's waters have been subject to climatically-induced fluctuations in level and hydrochemistry of variable magnitude, frequency and duration[8,11,12].

Holocene lacustrine sediments lie around the margins of the lake, up to 80 m above the present (July 1976) lake surface (~375 m OD). Although sediments north of the lake have already been examined[13-16], Holocene deposits from the other shorelines have previously received little attention. North-east of the lake near Koobi Fora (Fig. 1), they are informally termed the 'Galana Boi beds'[17-21].

Geology and lithofacies of Galana Boi beds

The Galana Boi beds are a sequence of predominantly lacustrine and marginal lacustrine, poorly consolidated, diatomaceous silts and sands. They rest unconformably on Plio–Pleistocene sediments over an area of ~2,000 km^2. Where exposed, they are mostly <10 m thick, but attain an aggregate thickness of 32 m in Area 103 (Fig. 1). The deposits lie up to 80 m above the modern lake and are unaffected by tectonics, except locally near the Kokoi uplands (Fig. 1), where they have been uplifted.

Littoral sandy units crop out as discontinuous curvilinear

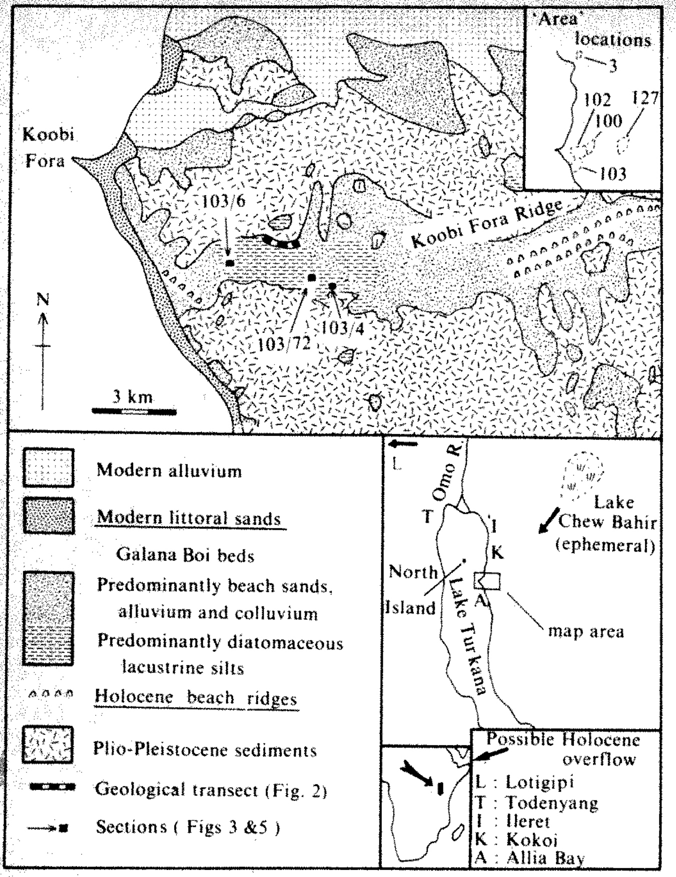

Fig. 1 Simplified geological map showing the distribution of the Galana Boi beds, east of Koobi Fora. Area numbers shown in the inset refer to fossil-collecting areas as designated by the Koobi Fora Research Project.

bodies parallel to former shorelines, while lacustrine silts have infilled palaeovalleys. Fluctuating lake levels during deposition have contributed to the development of lenticular and interdigitating sedimentary units, displaying vertical and lateral facies variations over short distances. Though commonly horizontal, primary depositional dips of up to 15° have developed where sediments drape over topographic highs.

Nearshore, moderate- to high-energy environments such as beach bars, barriers and sandy littoral shelves, are represented by a sublitharenite-quartz arenite lithofacies[10]. These heterogeneous sediments are typically well sorted (locally with distinct heavy mineral laminae) and although commonly massive due to bioturbation, many kinds of stratification are present. Typically they form linear bodies <2 m thick. Molluscs are common and include *Mutela emini*, *Etheria elliptica* and *Pila ovata*. Calcified root-tubules[22] and fish bones are locally numerous.

Distal alluvial and delta plain environments, and parts of shorelines adjacent to river mouths, are associated with a litharenite-arkosic arenite lithofacies[10]. This encompasses various sublithofacies that are moderately to poorly sorted. Stratification is generally poor and units are usually <2 m thick. $CaCO_3$ concretions, rhizoliths, root-marked palaeosols, molluscs, fish and other vertebrates are locally present.

Low energy lacustrine environments are represented by a diatomaceous silt, clay and fine sand lithofacies. The sediments are commonly well laminated (up to 1 cm), locally fissile and attain a maximum thickness of about 20 m. Diatom content ranges up to 10^8 individuals per g of sediment. Nitratine ($NaNO_3$) locally forms up to 8% of the deposits in Area 103. Molluscs are common and are dominated by *Melanoides tuberculata*, *Corbicula africana*, *Cleopatra pirothii* and *Bellamya unicolor*. Carbonaceous root-marks, calcite-cemented siltstone nodules, fish bones, pollen, sponge spicules and ostracods also occur.

There are three important biogenic lithofacies. In the first, *Etheria elliptica* forms reefs up to 4 m thick. Their relationship to other facies indicates a high-energy environment. In the second, *Melanoides tuberculata* and *Corbicula africana* variously dominate in silty sand units <10 cm thick. The degree of shell wear shows that both *in situ* and reworked assemblages are present. Third, a few outcrops of impure diatomite record former lagoons and areas of low clastic input.

Stratigraphy and chronology

Much of the data presented here originate in Areas 102 and 103 (Fig. 1). The stratigraphy of Area 102 is summarized by the transect in Fig. 2. The stratigraphies of Area 103 and other localities are shown in Fig. 3. Many new radiocarbon dates have been obtained[23] from the region and are listed in Table 1. The time-spans represented by the sections (Figs 2, 3) are shown in Fig. 4, together with a generalized plot of former lake levels against time. For descriptive purposes, three high level phases are recognized. These 'phases' do not represent continuously stable levels, but periods of varying duration in which the lake was high and fluctuating between +50 and +80 m.

Early Holocene sedimentation (phase 1): The diatomaceous silts of section C in Area 102 (Fig. 2) record a period of high lake levels (+75 to +80 m). They thicken to the east and south, and probably represent a large part of the early and middle Holocene. To the south-east, the basal units have been dated at 9,880 ± 670 yr BP (ref. 24) (section 103/4, Fig. 3).

South of the Kokoi uplands (Fig. 1), dates of 9,540 ± 260 and 9,260 ± 235 yr BP have been obtained from molluscs in high level spits (uplifted to +95 m). In the same area, mammal bones from littoral deposits have yielded ages of 8,395 ± 270 and 8,355 ± 235 yr BP.

Shells from littoral sands (+70 to +80 m) near Ileret (Fig. 1) have been dated at 9,360 ± 135 yr BP (ref. 17). Locally, these sands contain abundant stromatolites[10,25,26] (section 3/42, Fig. 3). In Area 127 (Fig. 1), subarkosic sands, silts, clays and impure diatomites represent former littoral and lagoonal environments. Shells from these deposits (+73 to +75 m) have yielded ages of 8,710 ± 130 and 8,520 ± 130 yr BP, while fish bone has given a date of 7,855 ± 160 yr BP. Locally, these sediments are overlain by reefs of *Etheria elliptica* (section 127/52, Fig. 3), which have given erroneous modern ^{14}C ages.

The dates reported above show that phase 1 (Fig. 4) accords with the high lake levels widely recorded in East Africa[1-6] for the early Holocene (~10,000–7,500 yr BP).

Middle Holocene sedimentation (phase 2): Following the early Holocene lake maxima, Butzer[16] found evidence in the Omo region (Fig. 1) for a fall to modern levels at 6,600 yr BP. Although the diaton record from section103/72 (Fig. 5) does suggest a regression that could relate to such an event, we lack evidence for a drop of such magnitude. This regression (Fig. 4) was followed by the higher, fluctuating levels of phase 2.

Phase 2 littoral deposits lie at ~+70 m in Area 103 (5,060 ± 245 yr BP) [24] and +67 m, 5 km north-east of Koobi Fora (4,540 ± 230 yr BP)[27]. Several dates (3,960 ± 60, 3,945 ± 135 and 4,100 ± 125 yr BP) have been recorded from littoral sands at +45 to +47 m (GaJi 4, Fig. 2). These units overlie diatomaceous clayey silts and silts (with *Stephanodiscus* and *Melosira* dominated diatom floras, Fig. 2) that formed under an expanded lake whose shoreline (~+55 m) may be marked by the planar cross-stratified sands of section B (Fig. 2).

Phase 2 represents a middle Holocene period of high (up to ~+75 m) fluctuating lake levels. However, the later stages were characterized by lower elevations of ~+50 to +55 m (Fig. 4).

Late Holocene sedimentation (phase 3): Phase 3 (Fig. 4) is recorded by 6 m of white, highly diatomaceous, laminated silts (section 103/6, Fig. 3), 5 km south-east of Koobi Fora. The base of this sequence lies at ~+35 to +40 m. Its stratigraphical relationship to sediments dated further east indicates a late Holocene age. An interbedded white vitric tuff (8 cm thick) probably represents a contemporary ashfall into the former

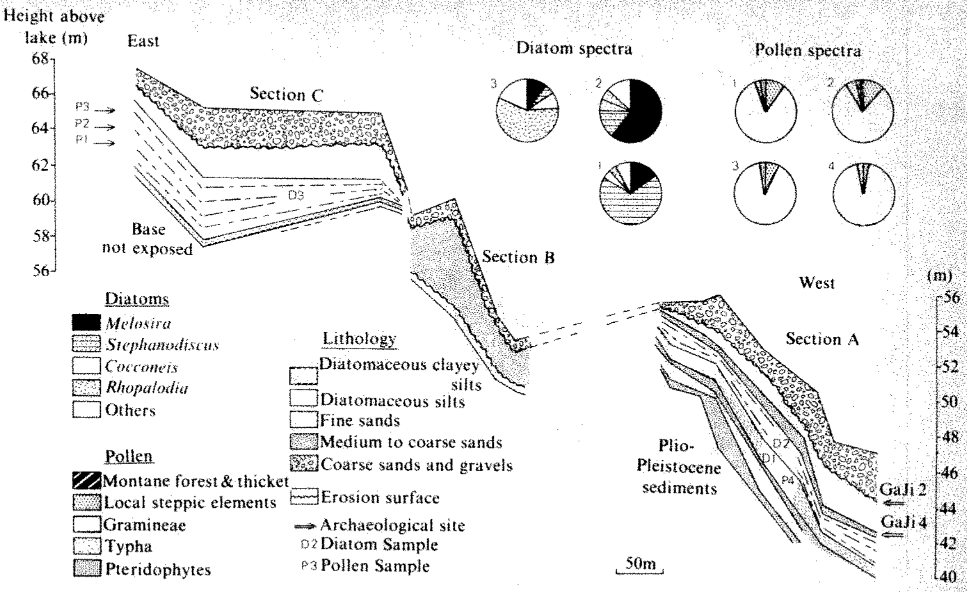

Fig. 2 Geological transect and representative microfossil spectra from Area 102. The location of the transect is shown in Fig. 1. The three sections were accurately levelled relative to one another and then related to the height of the lake surface (in July 1976) by using a barometric altimeter.

lake. One possible source may be the North Island volcano (Fig. 1), where trachytic lavas[28] overstep high-level, wave-cut platforms of probable early or middle Holocene age. An ill-defined series of beach ridges and regressive littoral sands record lower, fluctuating lake levels for the past two millennia.

Although the third phase remains to be dated radiometrically, it may be of broadly similar age to a late Holocene high stand recognized in the Omo region at 3,250 yr BP (ref. 14).

Other confirmed and probable Holocene lake sediments at +75 to +80 m have been reported from the southeastern[29], southwestern[30] and western[31–33] lake margins.

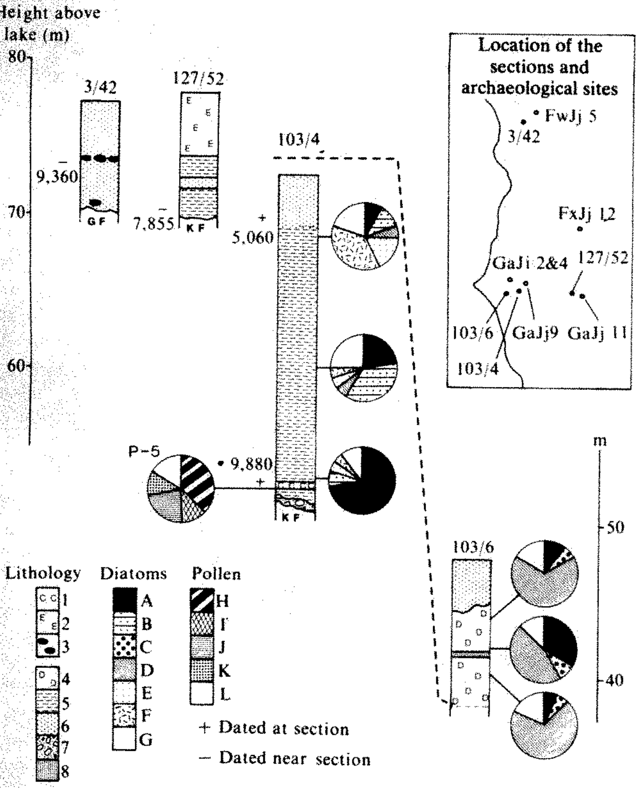

Fig. 3 Simplified litho- and microfossil stratigraphy of the Galana Boi beds. Lithologies: 1, coquina; 2, *Etheria* reef; 3, stromatolites; 4, impure diatomites; 5, diatomaceous silts; 6, sands; 7, orthoconglomerates; 8, tuff. The base of section 103/6 is not exposed. GF, Guomde Formation; KF, Koobi Fora Formation. Diatoms: *a*, *Melosira*; *b*, *Stephanodiscus*; *c*, *Cyclotella* and *Thalassiosira*; *d*, *Fragilaria*; *e*, *Cocconeis*; *f*, *Rhopalodia*; *g*, others. Pollen: *h*, montane forest and thicket; *i*, local steppic elements; *j*, *Gramineae*; *k*, *Typha*; *l*, *Pteridophytes*; *m*, others.

Diatom stratigraphy and lake palaeoecology

Figure 5 shows the diatom stratigraphy of section 103/72, which lies 9 km south-east of Koobi Fora (Fig. 1). Its base lies at ~+50 m and lateral tracing to locally dated units (section 103/4, Fig. 3) brackets it between ~9,880 and 5,060 yr BP (ref. 24).

Abundant planktonic diatoms in the lower 3.8 m of section 103/72, combined with a scarcity of benthic and epiphytic species, suggest a period of deep water and high lake level (phase 1). Lower levels are indicated by a dramatic decline in the planktonic species *Melosira agassizi* and *M. granulata-agassizi*, and by an increase in shallow water forms such as *Rhopalodia vermicularis* and *Cocconeis placentula*.

An increase in the planktonic component (dominated by *Stephanodiscus*) between 6 and 6.5 m reflects a second high level period, after which the lake was generally lower, but still covering the section site. Two, probably short-lived, transgressions can be inferred from increases in *Stephanodiscus minutula* (formerly *S. astraea v. minutula*) at 7.9 m and *Melosira nyassensis v. victoriae* at 7.2 m. At the top of the section, a decrease in diatom abundance, increasing grain size and littoral sands all indicate a fluctuating, regressing lake.

Although the basal silts of section 103/72 are certainly early Holocene, a lack of datable material at the top of the silts (10 m) has left the section open to two possible interpretations. First, the silts could be entirely of early Holocene age, the decline in *Melosira* at 3.8 m recording an early Holocene regression. This implies a very high average sedimentation rate of at least ~1 m 300 yr^{-1}, with even higher rates to the south and west where the silts thicken to ~20 m. Alternatively, the *Melosira* decline could reflect the fall in lake levels between phase 1 and phase 2 recorded elsewhere (Fig. 4). The subsequent transgression would then be of middle Holocene age, the record ending at ~5,000 yr BP. If the latter interpretation is correct, then the altimetric data, diatom stratigraphy and continuity of silt sedimentation would indicate that the lake did not fall below about +50 m for any extended period between ~10,000 and 5,000 yr BP.

The youngest diatomaceous units (phase 3 in Fig. 4; section 103/6 in Fig. 3) contain a flora dominated by *Fragilaria* spp. and *Melosira granulata*, but significantly include a few *Thalassiosira rudolfii* and *Cyclotella meneghiniana* for the first time. The latter diatoms occur in the modern saline, alkaline lake[10].

Ecological studies of modern East African diatoms[34–38] allow several inferences to be made concerning the former hydrochemistry. Today, Lake Turkana is saline (2.5 g l^{-1}) and alkaline (19–25 mequiv. l^{-1}) with a pH of ~9.2 and a SiO_2 concentration of ~18 mg l^{-1} (refs 7–9). The early and middle Holocene diatoms imply alkalinities ($HCO_3^- + CO_3^{2-}$) of ≤10 mequiv. l^{-1}, salinities below 2 g l^{-1}, a pH of ~7–8.5 and fluctuating SiO_2 concentrations of from ~1 to 10 mg l^{-1}.

Pollen of the Galana Boi beds

Figures 2 and 3 give the locations of five samples from which pollen was obtained. Sample P-5 is of early Holocene age, while the younger P-1 to P-4 material extends into the middle Holocene.

The oldest pollen spectrum was extracted from the base of a coquina dated at 9,880±670 yr BP (section 103/4, Fig. 3). It is characterized by abundant regional elements—montane forest and thicket taxa (36.8%), which do not occur in modern lake samples[39]. The pollen grains were probably transported to the lake by rivers originating in the Ethiopian Highlands. They suggest both increased runoff and an extension of the highland forests. This, together with a high percentage of *Pteridophytes* (14.7%), suggests increased rainfall over the catchment. Arboreal forms are uncommon (3.2%) among local elements, which are dominated by herbaceous types, notably *Gramineae* (21.2%) and *Compositae* (7.4%). The *Chenopodiaceae/Amaranthaceae*, which indicate saline soils, occur in low percentages (2.2%).

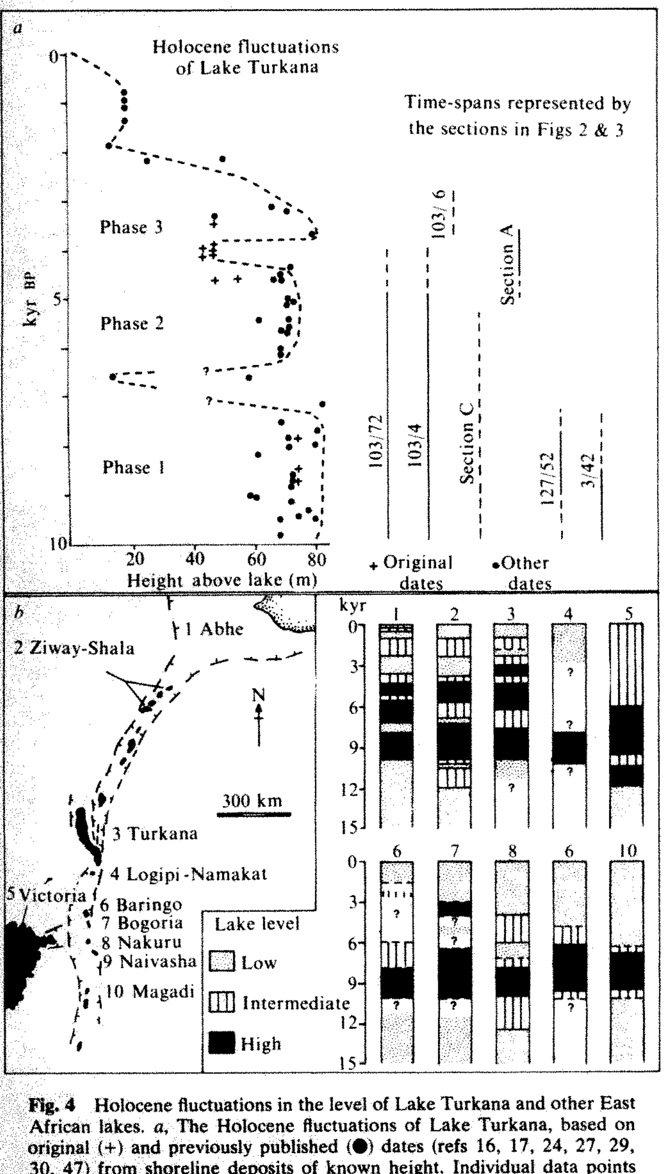

Fig. 4 Holocene fluctuations in the level of Lake Turkana and other East African lakes. *a*, The Holocene fluctuations of Lake Turkana, based on original (+) and previously published (●) dates (refs 16, 17, 24, 27, 29, 30, 47) from shoreline deposits of known height. Individual data points have not been joined together as this process can introduce a false sense of accuracy. The dates themselves commonly have error ranges of ±100–200 yr. Several dates from a single unit at the same level may give a wide variation. Dates from archaeological site GaJi 4 for example, range from 3,405 to 4,580 yr BP, with an exceptional date of 10,320 yr BP (probably from reworked material). As more dates become available so problems of scatter become apparent. For these reasons, we have traced only the general trends based on clusters of dates. *b*, Lake level trends for other East African lakes during the past 20,000 yr (includes original data for lakes Turkana, Baringo and Bogoria. Other sources: refs 1, 5, 49 and 56).

Samples P-1 to P-4 (sections A and C, Fig. 2) are younger and very different. They are dominated exclusively by taxa that typically inhabit lake margins in sub-desert zones[40]. Regional elements are absent or rare (0.4% in P-2) with only two taxa, *Juniperus* and *Myrica*, being represented. The occurrence of *Typha* and *Pteridophytes* in percentages >1% suggests the presence of rivers, although runoff was probably less than in the early Holocene. Local arboreal elements are rare (0.2–0.4%). Among local herbaceous forms, *Gramineae* are very abundant (77–99%). The *Chenopodiaceae/Amaranthaceae* again occur in low percentages (2.7% maximum). In two samples *Tribulus* constitutes 8.4–10.1% of the total pollen sum (P-2 and P-4, Fig. 2). This herbaceous taxon is today associated with refuse tips and is widely distributed in sub-desert zones[41]. Its occurrence may reflect the presence of local human encampments.

The early and middle Holocene lake margins were covered by a sub-desert steppe with well developed, herbaceous vegetation similar to that of today, although arboreal forms were more common at 9,880 yr BP. The poor representation of *Chenopodiaceae/Amaranthaceae* and the occurrence of *Typha* and *Pteridophytes* indicates the presence of freshwater rivers, supporting the other evidence for a lake less saline than today. The distribution of regional pollen suggests a more humid environment at 9,880 yr BP, but by the middle Holocene, climatic conditions had become more comparable with those of the present.

Archaeology

Two principal human economic adaptations are represented in the Holocene deposits. First, associated with early Holocene beaches, and continuing through into the middle Holocene deposits, are a distinctive set of lacustrine based occupations. Faunal refuse consists primarily of fish bones, while cultural materials include barbed bone harpoons and, at some sites, decorated and undecorated pottery. Seven large occupations are situated on the +75 to +80 m shoreline. Dates of 8,710±130 yr BP (GaJi 11, Fig. 3) and 8,395±270 yr BP (FxJj 12, Fig. 3) have been obtained from two of the sites. Importantly, ^{14}C ages of 9,540±260 and 9,260±235 yr BP were obtained from a basal *Melanoides* coquina at FxJj 12. This horizon contains a low density scatter of microlithic artefacts and fish-bone refuse. While the small excavation did not yield barbed bone harpoons, the lithic material indicates that by 9,500 yr BP, human groups with characteristic Later Stone Age lithic artefacts, were camping adjacent to the +75 to +80 m shoreline.

The lacustrine based sites exhibit broadly similar technological and economic features. The lithic assemblages are primarily composed of microlithic elements (especially crescents and curved backed blades), morphologically unstandardized scrapers, *outils écaillés* and core tools. Barbed bone harpoons, including uniserial, biserial and triserial examples, have been recovered. Two sites (FxJj 12 and GaJi 11) lack pottery remains suggesting a possible aceramic occupation phase. Decorated and undecorated pottery is represented at the remaining five shoreline sites. Numerous sherds similar to the well known 'wavy-line' pottery from the Sudan[42] are present at FxJj 12-North[43]. Fish remains, primarily several species of catfish and Nile Perch, constitute the major proportion of faunal refuse. Hippopotamus and crocodile, in addition to a wide variety of land mammals, are also represented. While freshwater molluscs, including such edible species as *Pila ovata* and *Etheria elliptica*, are commonly associated with the lacustrine sites, direct evidence for their consumption is lacking. Archaeological sites with similar lacus-

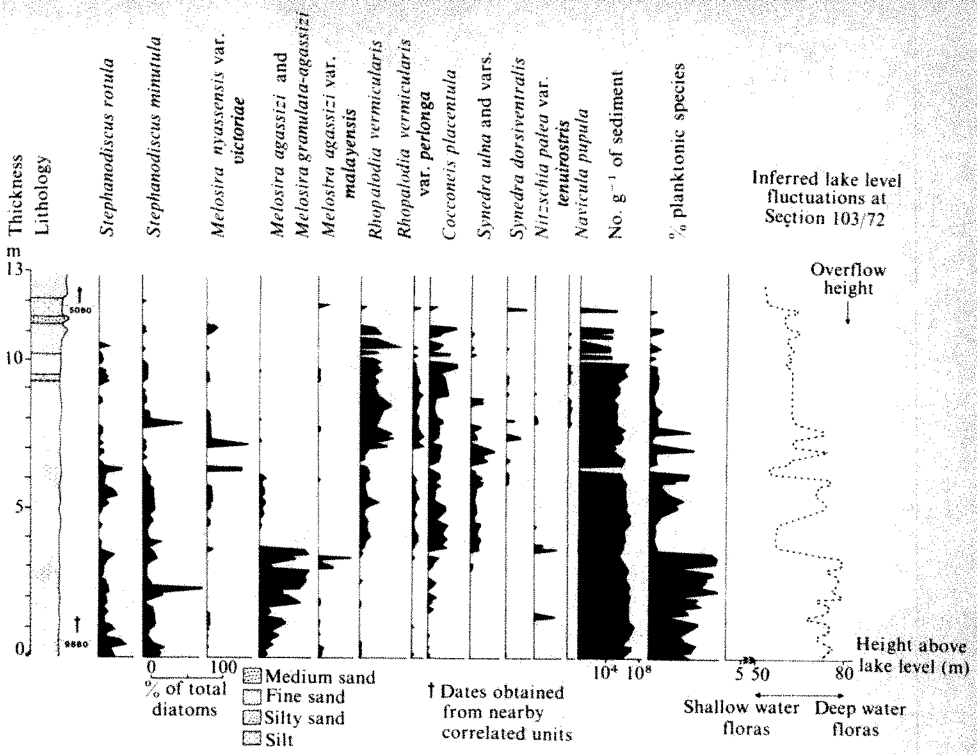

Fig. 5 Lithofacies, diatom stratigraphy and interpretation of section 103/72, north-east Turkana. The section site is shown in Fig. 1. Many species are present (96) but only the most important are included. The first five are planktonic types, whereas the remainder tend to be associated with shallow waters in East Africa. The lake level interpretation is relevant to the section site only, the base of which lies at about +50 m (barometric determination). The minimum and maximum levels of the fluctuation curve are provided by the known height of the section and the overflow level of Lake Turkana respectively. Within these limits the curve is generalized from the diatom data.

trine adaptation are known from the northern[16,44], south-western[30] and southeastern[29] margins of the basin.

The second principal economic tradition, the Pastoral Neolithic, is associated with the second phase of high lake levels. Domestic stock, including ovicaprids and probably cattle, are present at sites GaJi 2 and GaJi 4 (Fig. 3). A suite of ^{14}C determinations (Table 1) date the occupations to ~4,000 yr BP. These dates currently represent, along with preliminary dating results from North Horr[45], the earliest securely dated evidence for domestic animals in Eastern Africa[46]. At two sites, anomalously old shell dates of 8,915 ± 140 yr BP and 10,320 ± 150 yr BP have been recorded. These probably represent reworked debris and in both cases are associated with suites of younger dates from various materials.

Both pastoralist settlements lie within middle Holocene beach sands at +43 to +47 m. Stone artefact assemblages consist of typical Later Stone Age microliths and debitage. Several distinctive pottery types, including Nderit Ware, are represented. While fishing continued to play an important subsistence role, barbed bone harpoons are absent. The early pastoralists had apparently devised an alternative, as yet unidentified fishing strategy. Faunal remains of wild animals are noticeably scarce. A third pastoralist settlement, the Ileret Stone Bowl Site, yielded a single ^{14}C date of 4,000 ± 140 yr BP. Domestic cattle and ovicaprids are present in apparent association with stone bowls.

While little archaeological material is associated with the third phase, recent fieldwork to the south-west[47] suggests that human groups were pursuing a combination of aquatic and pastoral economic adaptations.

Discussion

Late Pleistocene high-stands are recorded for several East African lakes[1-5]. None has yet been recognized at Lake Turkana for the period 35,000–10,000 yr BP. This may reflect either a continuously low status or the erosion of any high-lake sediments that were deposited.

Lake Turkana expanded during the early Holocene, periodically reaching +80 m. Contemporary local hunter–gatherer groups camped adjacent to its fluctuating shorelines and increased their reliance on fishing.

Sandy silts at Todenyang (Fig. 1) that dip below the modern lake surface, have yielded a single mixed shell date of 6,600 ± 150 yr BP (ref. 14), which indicates a fall to modern levels during the middle Holocene. Although we do not reject this possibility, our experience of shells in the Turkana basin has shown that they may be reworked with little damage and should be interpreted with caution. If valid, the date implies major desiccation of a large lake at a time when the great majority of intertropical African lakes were at high or intermediate status[2,48]. No evidence has been found for significant contemporary erosion of the unconsolidated sediments in area 103 which span this period. Similarly, evidence is lacking for a fall of such magnitude to the south-east of the lake[29]. While accepting a possible drop to intermediate levels at this time, we lack evidence to confirm a fall to modern levels.

During the remainder of the middle Holocene the lake was fresh and fluctuated between high and intermediate levels. The local vegetation was dominated by *Gramineae* and by 4,500 yr BP, human groups with domestic animals were present.

Lake Turkana contracted during the late Holocene and became significantly more alkaline. While we have evidence for a lake standing at about +50 m, we lack data to confirm the rise to +75 m at 3,250 yr BP suggested by Butzer[16]. The lake level oscillated below about +50 m after 3,000 yr BP (refs 16, 30) (Fig. 4).

The lake demonstrates hydrological variability both in time and space. Hydrodynamic variations and consequent differences in the nature of the surface level record around the lake, partly reflect the influence of prevailing easterly winds. High energy shorelines predominate to the west, whereas more mixed energy environments occur to the east. The diatom record suggests that many minor oscillations were superimposed on the major fluctuations. In addition, alternating light and dark laminae in silts may reflect a cyclic input of flood waters, similar to those from the modern Omo River.

The lake level fluctuations can be mostly attributed to variations in the water balance caused by climatic change. The lake may have increased its catchment for periods during the early and middle Holocene by receiving overflows from Lake Chew Bahir[49] (Fig. 1) and a former lake in the Suguta Valley to the south[50,51]. At its maximum level (+80 m), Lake Turkana overflowed into the Lotigipi Plain (Fig. 1) and thence to the River Nile[16,52].

The archaeological data may provide a geographical and chronological link between the early food-producing traditions

M, Mammal bone; F, fish bone; H, human bone; Un., university. Heights quoted are based on barometric determinations. Site locations shown in Figs 1 and 3. For consistency with previous research, all shell dates are recalibrated to give an age 400 yr younger than that obtained by ^{14}C assay (for explanation, see ref. 14). The Ileret date of 9,360 yr BP is quoted as published as we have not been able to confirm any recalibration.

* Reference number.

in the Sudan and later pastoralist occupations in the central Kenya Rift. The appearance of early pastoralism in the Turkana basin may have been the result of small-scale population movements caused by middle Holocene climatic deterioration in the Sahel and Savannah zones, or the diffusion of pastoralist tradition[4]. Ehret[53] indicated that the linguistic evidence supports an ancestral Southern Cushitic identity for these early pastoralists. While this evidence is being evaluated[54], the archaeological data from the Turkana basin seem to support the Cushitic model[23,30].

An alternative model for the beginnings of pastoralism in East Africa has been proposed by Nelson (ref. 55 and unpublished data). He has uncovered evidence of domestic cattle some 40 km to the south of Nairobi, reported to date between 14,000 and 15,000 yr BP. This date would require rewriting of the history of animal domestication worldwide. However, it is based on a single ^{14}C determination on bone apatite (from our experience, a sometimes unreliable dating material) and faunal elements studied only in preliminary form. While a challenge to other models of early domestication in East Africa, including that presented here, more ^{14}C dates and extensive comparative examination of the fauna are needed before the far reaching implications of Nelson's work can be accepted.

Cosmids containing H-2 *histocompatibility antigen genes of the* H-2^{b} *haplotype have been isolated. One of these genes expresses a 45,000 molecular weight protein, indistinguishable from* H-2K^{b} *when introduced into mouse L cells. These* H-2K^{b} *transformed L cells can be killed by allospecific anti-*H-2K^{b} *cytotoxic T cells. Moreover, when infected with influenza virus, they can be killed by an* H-2K^{b}*-restricted, influenza virus-specific cytotoxic T cell line. These results show that expression of the* H-2K^{b} *gene product on the L-cell surface is sufficient to make it a target for specific T-cell killing.*

CELL-surface glycoproteins encoded by the genes of the major histocompatibility complex (MHC), *H-2* in mouse, *HLA* in man, are important in regulating cell–cell interactions, especially those governing the functions of the immune system[1]. Class I molecules, of which the best characterized are encoded by genes on the H-2K, D and L regions (Fig. 1*a*) act as guides for presenting extrinsic antigen (for example viruses) to cytotoxic T cells, whilst class II molecules encoded by genes in the I–region perform a comparable function for T helper cells[1]. How extrinsic antigens are presented in association with self-MHC molecules is still very poorly understood, partly because the structure of the T-cell receptor is unknown. However the problem can be approached by study of MHC molecules themselves. Knowledge of the amino acid sequence and three-dimensional structure of these molecules has progressed very rapidly over the past few years (see, for example, ref. 2). The *H-2K* and *H-2D* gene products are highly polymorphic, which may reflect the importance of genetic variation of MHC molecules in overcoming virus infections. The mutation rate, particularly of class I H-2 molecules is extremely high[3] and of all of the *H-2* haplotypes studied, that of *H-2^{b}* is the highest. Within this haplotype it is the *H-2K^{b}* molecule which undergoes mutational change most frequently. Nathenson *et al.*[4] have determined the complete polypeptide sequence of the H-2K^{b} molecule of C57BL/10 mice and have also determined portions of the sequence of several mutants[5] which express an altered H-2K^{b} molecule. Information about the DNA coding for these molecules is thus of great interest, and may give insight into the mechanism of mutation and generation of new haplotypes.

Several groups have isolated cDNA[6,7] and genomic DNA clones[8-10] containing class I *H-2* or *H-2* related DNA sequences from BALB/c mice (*H-2^{d}* haplotype). We have isolated ~100 different cosmid clones, containing sequences mapping to the *H-2* and associated regions (Fig. 1*a*) of chromosome 17 from a cosmid library constructed using spleen DNA from C57BL/10 mice (*H-2^{b}* haplotype). A full description of the construction and screening of these libraries together with chromosomal mapping data for all the *H-2*-related cosmid clusters, will be given elsewhere. Here we describe a cluster of five overlapping cosmids (the H8 cluster) and show that one of the two *H-2* gene sequences cloned in this cluster encodes a cell-surface antigen which is recognised by *H-2K^{b}* restricted T cells. It therefore appears identical to the *H-2K^{b}* polypeptide found on cells derived from C57BL/10 mice.

Restriction map of the H8 cosmid cluster

The H8 cluster of cosmids consists of five overlapping cosmids containing two class I *H-2* related genes, approximately 15 kilobases (kb) apart, which hybridize to human genomic[11] and *H-2* cDNA class I gene probes[6] (Fig. 1*b*). The DNA cloned in this cluster spans about 65 (kb) of the C57BL/10 genome and the two *H-2* class I gene-related sequences are arranged in a head to tail configuration, as determined by hybridization to 5′ and 3′ probes obtained from the *HLA* or *H-2* probes. The left-hand gene (*H-2* genes are defined here as DNA sequences which hybridize to *HLA* and *H-2* class I probes) is present in cosmids H8, H25, H24 and H39 (A gene), whereas the right-hand gene sequence (B gene) is present only in H8 and H21. As polymorphic restriction site mapping of this cosmid cluster shows that the cloned region is derived from the *H-2K* (Fig. 1*a*) end of the *H-2* complex (manuscript in preparation), we investigated whether one (or both) of the two gene regions in the H8 cluster encoded an *H-2K^{b}* cell-surface antigen. Thus, we have introduced each cosmid into mouse Ltk^{-} (of *H-2^{k}* haplotype) cells using CaPO$_4$-mediated DNA transfer and tested the resulting tk^{+} clones for expression of new H-2^{b} cell-surface antigens using (1) direct monoclonal and allo-antibody binding (2) antibody-dependent complement-mediated lysis and (3) alloreactive anti-H-2K^{b} T-cell mediated lysis (CML) and (4) H-2K^{b}-restricted virus specific T-cell killing.

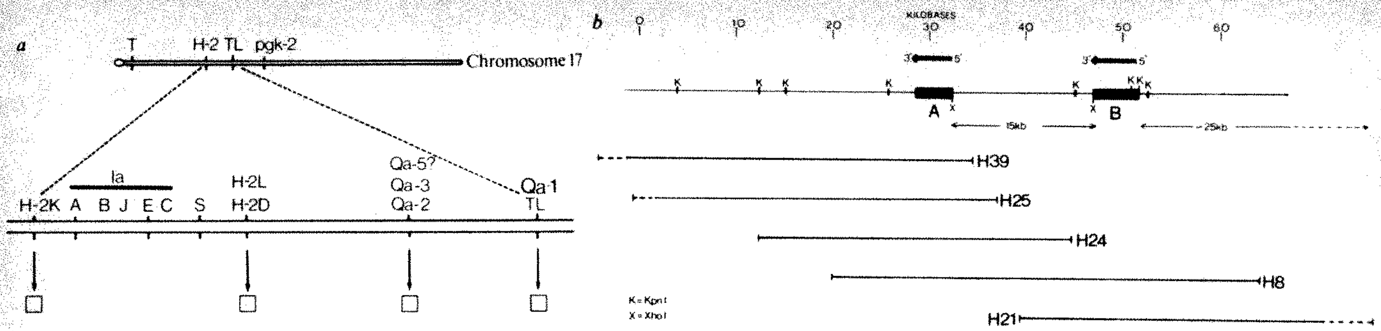

Fig. 1 *a*, Genetic map of the mouse *H-2* and associated genetic loci. The top line shows a diagram of chromosome 17 with the centromere on the left. The bottom line shows an expanded diagram of the regions between the *H-2K* locus on the left and the TL locus on the right. H-2 class 1 molecules (□) are expressed from at least four separate genetic loci as shown by the arrows below this line. *b*, A restriction enzyme map of the region cloned in the H8 cosmid cluster. The top line shows the extent of the cloned region and the approximate positions of *Xho*I(X) and *Kpn*I (K) restriction sites (see top scale calibrated in kilobase, kb). Class 1 gene regions (A and B) are shown as thick lines and their 5′ to 3′ orientation is indicated by the thick arrows over the line. The approximate extent of each cosmid is shown below the line beside the name assigned to each cosmid. Dotted lines at the end of cosmids indicate that the end of the cosmid has not been determined precisely.

Table 1 Antibody-dependent cytotoxicity assays

Antisera/antibodies		% Specific ^{51}Cr release (cell lines) Ltk$^-$	LH8	LH39
WS9/7B (αK^k)		73	71	61
D32(αD^k) NIH		63	71	61
D1 (αH–2^k) NIH		58	72	66
D8 (αH–2^k) NIH		21	70	44
100-5 (anti-H–2.11/αH–$2K^k$) monoclonal*		62	50	44
Anti-H–2.33 (αK^b)	NIH unabsorbed	2	72	6
(Ia–9–20)	B10 absorbed	0	0	0
	AKR absorbed	2	66	0
D28 (αH–2^b)	NIH unabsorbed	21	70	44
	B10 absorbed	1	1	0
	AKR absorbed	2	48	0
27–11–13 (αD^b)†		4	6	0

The chromium release assay was performed essentially as described by Sanderson[19]. Details of all antisera and monoclonal antibodies except 100–5[20] and 27–11–13[21] can be found in ref. 14. Absorptions of antisera were carried out before binding to cell lines using either C57BL/10 (B10) or AKR lymphocytes. Cell lines tested for lysis in this experiment were untransformed L cells (Ltk$^-$) and uncloned tk$^+$ cells transformed by cosmid H8 (LH8) or cosmid H39 (LH39). % Specific ^{51}Cr release was measured as (test c.p.m. − spontaneous c.p.m./maximum c.p.m.) × 100. Spontaneous release was 10–13%. Numbers shown in a box are significant results showing specific H-2K^b expression.

* Lemke *et al.*[20].

Introduction of cosmid DNA

The cosmid library used in this study was constructed using the cosmid vector pOPF1 (F. Grosveld *et al.*, in preparation). As this vector contains the herpes simplex virus thymidine kinase (*tk*) gene, cosmid DNA can be selected for its presence in transformed L cells by growing the cells in hypoxanthine/aminopterin/thymidine (HAT) medium. Thus, the five cosmids from the H8 cluster were used to generate tk$^+$ clones following CaPO$_4$-mediated DNA transfer and subsequent selection for tk$^+$ clones in HAT medium[12]. For each cosmid transformation, two subclones were isolated and the rest of the tk$^+$ clones were passaged as an uncloned tk$^+$ population. We experienced some difficulty with cosmid H21, due to its propensity to lose DNA sequences whilst replicating in host bacteria.

Analysis of transformed L-cells

Binding of antibodies: L cells transformed by individual cosmids and established as stable Ltk$^+$ transformed clones growing in HAT medium, were tested for their ability to bind anti-H-2K^b or anti-H-2D^b monoclonal antibodies in ^{125}I-radioimmunoassays. The results of a binding assay using Ltk$^+$ cell clones derived by transformations with H8, H24, H25, H39 and a control, H11 (a cosmid which maps to the H-2 related TL region; in preparation) are shown in Fig. 2. Both clones derived from H8 transformations (LH8.1 and LH8.2) bind anti-H-2K^b monoclonal antibody at a level higher than that of the positive control EL4 cell line (an H-2^b fibrosarcoma cell line). All other cell lines tested show only background levels of anti-H-2K^b monoclonal antibody binding. Anti-H-2D^b monoclonal antibody was not bound to any of the cell lines tested. Recently, Goodenow *et al.*[13] and Evans *et al.*[16], have both detected the expression of a cloned *H-2L^d* gene in transformed cells by using a monoclonal antibody binding assay.

In addition, a series of well characterized anti-H-2 alloantisera was used. In this case, binding of antibodies to L-cell lines was assessed using either complement-dependent chromium (^{51}Cr) release (Table 1) or complement-mediated growth inhibition assays (Table 2).

These assays both demonstrate that L cells transformed with cosmid H8 express a cell-surface polypeptide which is recog-

Table 2 Antibody-dependent growth inhibition

Antisera/antibodies		% Specific growth inhibition cell lines L cells	LH8.1	LH39
Anti-H–2.23 (αK^k) NIH		74.8	85.8	87.3
100–30 (anti-H–2.25/$\alpha K^k D^k$) monoclonal*		78.8	89.6	93.5
Anti-H–2.28 (αH–2^b)	NIH unabsorbed	4.2	66.2	7.1
	B10 absorbed	NT	6.3	3.9
	AKR absorbed	NT	40.5	0
Anti-H–2.33 (αK^b)	NIH unabsorbed	0	86.4	0
	B10 absorbed	NT	0	0
	AKR absorbed	NT	86.9	0

NT, not tested. For sera see Table 1. B10 = C57BL/10. The growth inhibition assays were performed as described previously[22]. L cells were cultured in Cooke flat-bottomed microculture plates at 10^4 per well in 4 μl for 45 min at 37 °C in RPMI with 10% fetal calf serum in CO$_2$ and air with 1 μl of antibody per well (final dilution 1/5). Rabbit complement (1/5 diluted) was then added and the incubation continued for another 30 min. ^{14}C-uridine was added and the incubation continued for 6 h. 0.025% Trypsin in phosphate-buffered saline was then added and incubated for 30 min. After three washes the wells containing adherent cells were punched out and counted in a scintillation counter. Cell lines tested in this assay were untransformed L cells (Ltk$^-$), a cloned L-cell line transformed by cosmid H8 (LH8.1) and uncloned tk$^+$ cells transformed by cosmid H39 (LH39). Numbers shown in a box are significant results showing specific H-2K^b expression.

* Lemke *et al.*[20].

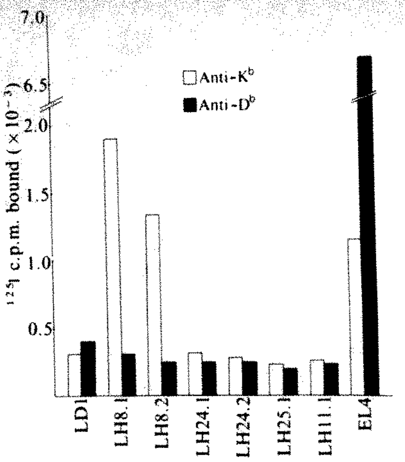

Fig. 2 Histogram showing the binding of monoclonal antibodies to transformed L cells. Binding studies were done in Titertek 96 well flexible plastic plates (Flow Laboratories). These were first blocked with radioimmunoassay RIA buffer (0.1 M phosphate-buffered saline, pH 7.2 plus 0.02% NaN_3 + 1% bovine serum albumin) and cells were assayed at 5×10^5 per well in triplicate. Cells were incubated with the first antibody in a volume of 100 µl of MEM-H (Eagle's minimal essential medium plus HEPES buffer + 0.1% NaN_3 + 5% calf serum) for 1 h at room temperature on a Titertek plate shaker (Flow), washed 3× with MEM-H and then incubated for 45 min with ^{125}I-labelled affinity purified sheep anti-mouse immunoglobulin (10–15 µCi per µg) in a volume of 100 µl containing ~10^5 c.p.m. per well. Cells were washed 3X and counted in a Nuclear Chicago γ scintillation counter. The monoclonal antibodies used were anti-H-2K^b(Y25, a gift of E. A. Lerner) used at a dilution of 1:2,000 or anti-H-2D^b (B22-249-R1, see ref. 23) used at a dilution of 1:100. LD1 cells are Ltk$^-$ control cells.

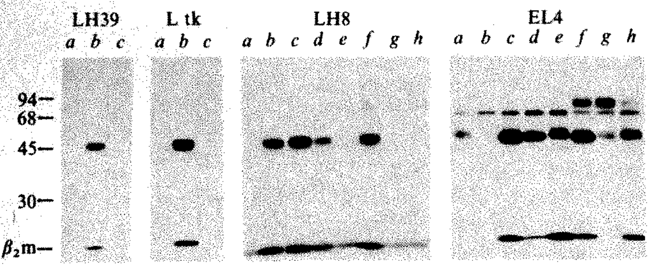

Fig. 3 Immunoprecipitation of radiolabelled cell-surface antigens from transformed L cells. Cell-surface proteins of cells indicated were radiolabelled with ^{125}I by the glucose oxidase–lactoperoxidase catalysed iodination technique[24] and lysed with nonionic detergent (0.5% NP40 in 0.01 M Tris-HCl buffer, pH 7.4, containing 0.15 M NaCl, 1.0 mM $MgCl_2$) in the presence of 1,000 KIE ml^{-1} Trasylol (soy bean trypsin inhibitor). Reaction of solubilized cell membrane proteins with monoclonal antibodies and alloantisera was determined by immunoprecipitation using *Staphylococcus aureus* and SDS-polyacrylamide gell electrophoresis of the resulting precipitates as previously described[25]. Precipitations were done with BALB/c-normal mouse serum (control) *a*, with monoclonal antibodies (refs. 19, 20) specific for H-2K^k (H100-5) *b*; H-2K^b (20-8-4s) *c*; H-2K^b, D^b (28-8-6s) *d*; H-2D^b, L^d(28-14-8s) *e*; and with alloantisera raised against the private specificities of H-2K^b *f*, *g*; and H-2D^b *h*. The anti-H-2K^b sera (A × B10.D2)F$_1$ anti-B10.A (5R)) were either preabsorbed with AKR (H-2^k) lymphocytes which remove antibody against murine leukaemia virus gp70 but not H-2 (*f*), or with B10 lymphocytes, which specifically remove anti-H-2K^b alloantibody (*g*). Note that both monoclonal antibodies and alloantiserum with specificity for the H-2K^b molecule precipitated a 46,000 molecular weight protein, which is identical in molecular weight to the H-2K^b expressed on EL4 (*H-2^b*) tumour cells. Co-precipitation of β_2-microglobulin (β_2m), incorporation of trititated mannose and glucosamine, and binding to *Lens culinaris* Sepharose (not shown) indicate that the cloned *H-2K^b* gene product is expressed on L cells in the same manner as in normal *H-2^b* lymphoid or tumour cells (ref. 4).

nized by public (anti-H-2.28) and private (anti-H-2.33) specificity alloantisera[14] reactive against the H-2K^b molecule. Antibody binding to these cell lines was shown to be specific for H-2^b antigens, because preabsorption of the antisera with spleen cells from B10, but not AKR (*H-2^k*) mice blocks binding. L cells transformed with cosmid H39, which contains the A gene, but not the B gene, do not express the public or private *H-2^b* determinants defined by the alloantisera we used. All cell lines, including untransformed Ltk$^-$ cells (which are derived from the C3H mouse of *H-2^k* haplotype) react with monoclonal antibodies and alloantisera directed against H-2^k cell-surface antigens. The data suggest that cell lines transformed with cosmid H8 express a cell-surface antigen which is indistinguishable from the H-K^b molecule using these antibodies. In addition, the lack of any significant anti-H-2K^b antibody binding to those cell lines transformed with cosmids H24, H25 and H39 suggests that the H-2K^b polypeptide detected in H8 transformed cells is expressed from the B gene in the cloned region.

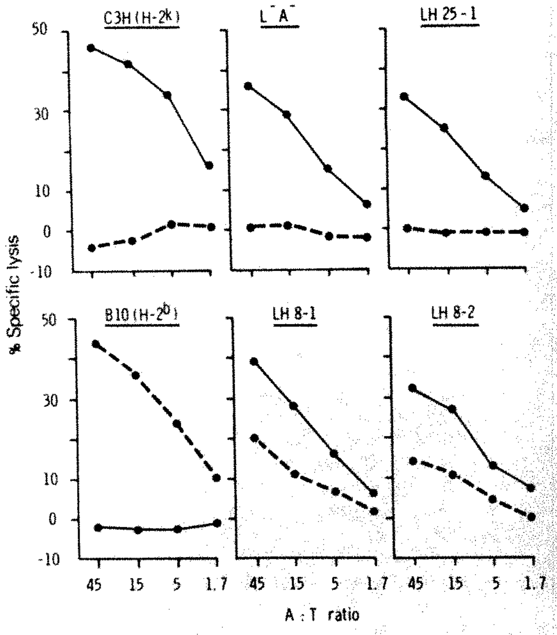

Fig. 4 1–2 × 10^6 target cells were labelled with 100 µCi ^{51}Cr-labelled sodium chromate for 1 h then washed twice. 1 × 10^4 Labelled target cells, in 100 µl volumes were placed in round-bottomed wells of microtitre plates. For the cytotoxic T-cell lysis (CML) killer cells, generated in 5-day mixed lymphocyte cultures (CBA anti-BALB.B = k anti-b, B10 anti-CBA = b anti-k) were added in 100 µl to give attacker: target (A:T) ratios of 45:1, 15:1, 5:1 and 1.7:1. Three triplicate wells of each A:T ratio were set up. After 5 h incubation at 37 °C in a 5% CO_2 humidified atmosphere the plates were spun and 100 µl of the supernatant from each well collected and counted for released γ counts. The per cent specific lysis was calculated according to the formula $(E - C/(M - C) \times 100\%$ where E = c.p.m. from target cells incubated with killer cells, C = c.p.m. from target cells incubated in medium alone and M = c.p.m. from target cells lysed with 5% Triton. L$^-$A$^-$ refers to control Ltk$^-$ cells.

Detection of H-2K^b in the L-cell membrane: Confirmation that L-cells transformed with cosmid H8 contain H-2K^b heavy chain polypeptides on the cell surface was obtained by labelling the cell surface proteins of transformed cells with ^{125}I and immunoprecipitating the cell extracts. This was done by using either alloantisera o monoclonal antibodies directed against the H-2K^b molecule. Immunoprecipitates were analysed by SDS–polyacrylamide gel electrophoresis and the results are shown in Fig. 3. The H-2K^d-specific alloantisera and two monoclonal antibodies (anti-H-2K^b and anti-H-2K^{b}D^b) precipitate cell-surface polypeptides of molecular weight 45,000 and 12,000 (H-2 heavy chain and β_2-microglobulin respectively) from extracts of L cells transformed with cosmid H8. No polypeptides were precipitated from the LH8 cells by the anti-H-2D^b/L^d-specific monoclonal antibody (Fig. 3, lane *e*).

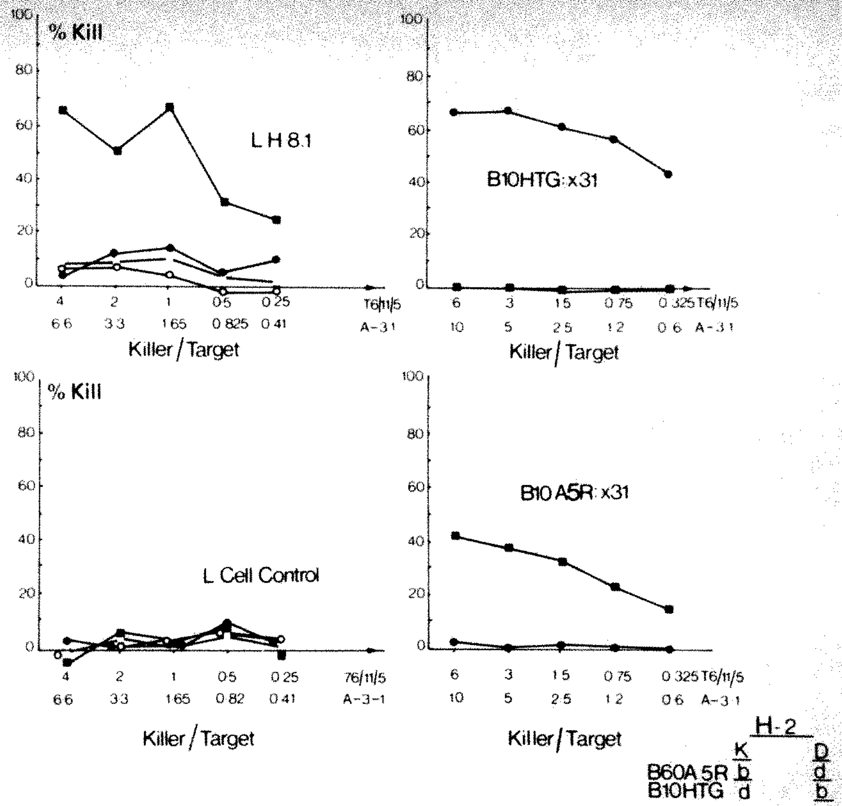

Fig. 5 T_c-cell mediated killing of transformed L cells infected with influenza virus. T_c-cell clones: The derivation of the two influenza-specific T_c clones T6/11/5 and A3.1 will be described in detail elsewhere (A.R.M.T. and P.M.T., manuscript in preparation). Clone A3.1 is restricted to H-2D^b and clone T6/11/5 to H-2K^b. In brief, C57BP6 mice were primed by ultranasal infection with A/X31 or A/JAP influenza virus. T_c-cell lines were established from spleen cell suspensions from these mice by repeated stimulation with 2,000R irradiated A/X31 infected syngeneic spleen cells, either in the presence (A3.1) or absence (T6/11/5) of a source of growth factors from concanavalin A-pulsed rat spleen. Cells from both sources were cloned at 0.5–10 cells per well onto 5×10^5 2,000R X31 infected syngeneic spleen in the presence of 10–20% concanavalin AS/N. 10–20 days later they were transferred to 2-ml wells and maintained by repeated antigenic stimulation with 2,000R X31 infected syngeneic spleen in the presence of 20% concanavalin AS/N every 5–10 days. Chromium release assay: Transformed and untransformed L cells were plated out at 3×10^4 per well in 100 μl α medium containing 10% fetal calf serum 18 h before assay into Nunc 96 well flat-bottomed wells plated in the presence of 2 μCi of sodium chromate (^{51}Cr). Before the assay the plates were spun at 1,000 r.p.m. for 5 min and the medium from wells containing cells to be infected removed by suction. To each of these wells was added 100 μl of serum free α medium containing 320 HA A/X31 and the plates incubated for a further 1.5 h. The plates were then washed four times with 200 μl per well balanced salt solution and the cells in all wells finally resuspended in 100 μl of RPMI medium plus 10% fetal calf serum. Control target cells were 3% thioglycollate-induced peritoneal exudate cells from B10A5R (*H-2K^b, D^d*) and B10 HTG (*H-2K^d, D^b*) mice. 10^7 cells were labelled with 100 μCi Na chromate (^{51}Cr) and infected with 3,200 HA A/X31 in 0.5 ml serum free RPMI for 1.5 h. Immediately before the assay they were washed four times in 10 ml phosphate-buffered saline and resuspended in RPMI 10% fetal calf serum. 2×10^4 targets were dispensed in 100 μl to wells of Nunc 96 well flat-bottomed microtitre plates. The cloned cytotoxic cells, at the ratio indicated in the figure, were added in 100 μl plus 10% fetal calf serum to experimental wells, 100 μl RPMI plus 10% fetal calf serum alone was added to control wells. The plates were spun at 1,000 r.p.m. for 1 min and then incubated for 6 h at 37 °C. The collection of ^{51}Cr-containing supernatants was done as previously described[26]. All samples were counted on a Wallac 80,000 γ counter for 2 min. Results were calculated as % specific ^{51}Cr release from target cells as follows:

$$\frac{\text{release in presence of cloned } T_c - \text{medium release}}{\text{Triton release} - \text{medium release}} \times 100\%.$$

All points are the mean from three identical wells. ○, Control target cells; A-3.1 H-2D^b (restricted) effectors. □, Control target cells; T6/11/5 (H-2K^b restricted) effectors. ●, Infected target cells; A-3.1 effectors. ■, Infected target cells; T6/11/5 effectors.

Anti-H-2K^b antibodies also fail to detect any polypeptides in untransformed Ltk$^-$ cells or in cells transformed with cosmid H39 which contains the A gene. Preabsorption of the anti-H-2K^b alloantisera using unlabelled B10, but not AKR lymphocytes prevents the precipitation of H-2K^b and β_2-microglobulin from extracts of cells transformed with cosmid H8 (Fig. 3, lanes *g* and *f* respectively).

Cytotoxic T-cell killing of L-cells: The presence of the H-2K^b molecule on a cell renders these cells as targets for allogeneic cytotoxic T-cell (T_c-cell)-mediated killing by T_c cells raised against H-2^b antigens[15]. A number of indirect arguments suggest that the presence on the cell membrane of a given H-2 polypeptide, such as the H-2K^b molecule is sufficient to generate a target for T_c-cells. For example, this process can be blocked by monoclonal antibodies directed against a single H-2 polypeptide[16]. To test this further, we generated T_c cells directed against H-2^b or H-2^k antigens and tested their ability to kill various target cells (Fig. 4, Table 3). Whereas anti-H-2^k T_c cells show specific killing of all L-cell lines tested, anti-H-2^b T_c-cells show specific killing of only control B10 target cells and two L-cell clones (LH8-1 and LH8-2) transformed by cosmid H8. Untransformed L cells (Ltk$^-$), a clone transformed by cosmid H25 (LH25-1) and other clones transformed by cosmids H24 and H39 (data not shown) were not killed by anti-H-2^b T_c cells. These data confirm that the H-2K^b molecule detected by serological assays in cosmid H8 transformed cells, can act as a target for anti-H-2^b T_c-cell killing.

We performed a similar experiment using B10.D2 (*H-2^d*) Tc cells generated by immunization with target spleen cells from the recombinant mouse B10.A (5R) *K^b, D^d*). Such T_c cells kill cells expressing the H-2K^b but not the H-2D^b molecule. These Tc cells also kill L cells transformed with cosmid H8, but not L cells transformed with cosmid H39 (Table 3).

Thus, these data suggest that the B gene present in cosmid H8, but not present in cosmids H24, H25 and H39, encodes a molecule carrying the determinant recognized by anti-H-2^b and anti-H-2K^b T_c cells.

T-cell killing of virus-infected L-cells: T_c cell mediated lysis of cells expressing viral antigens on their surface can only take place when the viral antigen is presented to T_c cells in association with an appropriate H-2 antigen; in this way H-2 antigens act as a restriction element for the T_c-cell response[15,17]. Thus, we tested the ability of the H-2K^b molecule expressed on the surface of L cells transformed by cosmid H8 to act as a restriction element for T_c-cell-mediated killing of influenza virus-infected cells.

Influenza-specific T_c clones restricted to one H-2 region can be selected and grown in the presence of T-cell growth factor[18]. L cells (*H-2^k*) and LH8-1 cells were infected with type A influenza virus (A/X31) and used as target cells for two influenza-specific H-2^b T_c clones, one restricted to H-2K^b (T6/11/5) and the other (A/3.1) to H-2D^b molecules (A. Townsend and P. M. Taylor, unpublished data). Figure 5 shows that X31 infected, untransformed L-cells (H-2^k) are unable to act as targets for killing by either the H-2K^b or H-2D^b restricted T_c-cell clones. LH8-1 cells infected with X31, however, act as targets for killing by the H-2K^b restricted T_c-cell clone, but not the H-2D^b restricted clone. This shows that the H-2K^b molecule expressed on the surface of LH8-1 cells is able to act as a restriction element for T_c-cell killing of X31 virus-infected cells.

Discussion

We have shown here that the H8 gene cluster contains two *H-2* genes, one of which (gene B) is an *H-2K^b* gene. The second gene (gene A) does not express a polypeptide that can be detected by any o the immunological criteria we have used

Table 3 Cell-mediated cytotoxicity

Cytotoxic T lymphocytes (CL) were generated *in vitro* from splenic lymphocytes of responder strain mice (B10.BR and B10.D2) which had been inoculated 1 week earlier with 4×10^7 stimulator strain (B10 and B10.A(5R) respectively) splenic lymphocytes. Responder lymphocytes were cultured in flasks at 2×10^7 per ml with an equal number of irradiated (2,000 rad) stimulator splenic lymphocytes in 10 ml culture medium (RPMI 1640 with 10% fetal calf serum, 100 U ml^{-1} penicillin, 10 μg ml^{-1} streptomycin, 5×10^{-5}M 2-mercaptoethanol). Cells were collected after 5 days' incubation at 37 °C in 8% CO_2 in air and assayed for cytotoxic activity against normal (L cells) or transfected (LH8, LH39) tumour cells labelled with ^{51}Cr-labelled sodium chromate. These cells were grown as monolayers and detached by treating for 5 min with 0.25% trypsin/versene in phosphate-buffered saline before being labelled with sodium chromate (100 μCi per 5×10^6 cells) for 2 h, washed four times to remove any free radioactivity, then suspended in assay medium (RPMI 1640 with 10% fetal calf serum) to 10^5 ml^{-1}. The CML assay was performed in round-bottomed microtitre plates. CL at 10^7, 5×10^6, 10^6 and 10^5 per ml were prepared and 0.1 ml samples added per well followed by 0.1 ml of transformed cell (TC) suspension. Plates were centrifuged at 100*g* for 45 s then incubated at 37 °C in 8% CO_2 in air. Each CL:TC ratio was performed in triplicate and controls for spontaneous release of radioactivity included (0.1 ml TC plus 0.1 ml assay medium). Maximum release of label was estimated by incubating 0.1 ml TC with 0.1 ml of 1% Triton X-100. After 4 h, plates were centrifuged again for 10 min to pellet cells and 0.1 ml supernatant collected from each well into small tubes for counting radioactivity released. The percent specific lysis or release was calculated as: (test c.p.m. − spontaneous c.p.m./maximum c.p.m.) × 100. Spontaneous release for all TC was ~12% and for all samples in the table the mean s.d. was 1.3, range 0.1–6.1. LH8 and LH39 are uncloned cell populations whereas LH8.1, 8.2 and 39.1 are cloned cell lines.

and may perhaps be a pseudogene. We have determined part of the DNA sequence which corresponds to the first and second domains of the A and B genes. While the sequence of the B gene is identical to that expected for an *H–2K^b* gene, the A gene shows only about 75% homology with this sequence (unpublished results). It is therefore clear that if the A gene does encode an H–2 protein, this protein is no more similar to the *H–2K^b* gene product than to any other H–2 molecule[4]. That the B gene is the *H–2K^b* gene is shown by a number of functional criteria. First, L cells transformed with the B gene from the H8 cluster express a 45,000 molecular weight polypeptide which carries determinants characteristic of the H–2K^b molecule and which reacts with a number of H–2K^b-specific monoclonals. This suggests that all the epitopes normally associated with the H–2K^b molecule are present on the surface of the transformed L cells. Second, L cells transformed with the B gene are recognized as targets for allogeneic (anti-H–2^b) T_c cell killing and for virus-specific, H–2 restricted T_c-cell killing of infected cells.

These results suggest that a detailed molecular analysis of the determinants recognized by antibodies and the T-cell receptor, using cells transformed with recombinant DNA will be possible. Specifically, L cells transformed with hybrid *H–2* genes, constructed *in vitro*, which contain DNA segments from, say, the *H–2K^b* and *H–2D^b* genes should help determine whether T_c-cell clones, either allospecific or H–2 restricted, can kill such target cells. In this way, we hope to map the determinants recognized by specific monoclonal antibodies and by the T-cell receptor.

We thank Professor N. A. Mitchison and Drs A. Fortunato (ICRF) and A. Alonzo for helpful discussions, B. Jordan, P. Kourilsky, M. Steinmetz and L. Hood for the probes, and Cora O'Carroll for preparing this manuscript. L.G. and E.W. were the recipients of postdoctoral fellowships from the Helen Hay Whitney Foundation and the Deutsche Forschungsgemeinschaft respectively. The work in the laboratories of R.A.F., E.S. and A.R.M.T. was supported by the MRC. Work in the laboratory of H.F. was supported by the Cancer Research Campaign and work in the laboratory of R.J. by the Imperial Cancer Research Fund.

Formation of transmembrane tubules by spontaneous polymerization of the hydrophilic complement protein C9

Jürg Tschopp, Hans J. Müller-Eberhard & Eckhard R. Podack

Department of Molecular Immunology, Research Institute of Scripps Clinic, La Jolla, California 92037, USA

The ninth component of complement C9 can undergo circular polymerization in the fluid phase and on lipid membranes. The concomitant hydrophilic–amphiphilic transition is the result of a conformational reorganization of C9 and allows insertion of poly C9 into membranes in the form of a transmembrane protein channel. The ultrastructure of poly C9 resembles that of membrane lesions caused by complement.

FIVE of the more than 20 complement proteins are directly involved in complement-dependent membrane damage and cytolysis[1,2]; these are C5, C6, C7, C8 and C9. Enzymatic cleavage of a single peptide bond in C5 initiates[3] self-assembly of the five proteins into a supramolecular organization termed the membrane attack complex (MAC) of complement[4]. Assembly proceeds from formation of the bimolecular complex C5b–6 to the reaction of C5b–6 with C7, which results in formation of the intermediate complex, C5b–7. After binding of C8 by C5b–7, the C5b–8 complex reacts with multiple C9 molecules, leading to the formation of the MAC. Assembly of the MAC results in the expression of hydrophobicity by the originally hydrophilic proteins. Hydrophobic protein domains seem to be responsible for the insertion of C5b–7 into target membranes[5] and for membrane damage caused by the binding to C5b–7 of C8 and C9 (refs 6, 7). Complement-induced membrane lesions can be visualized by electron microscopy as originally reported by Borsos, Dourmashkin and Humphrey[8]. By negative staining, an individual lesion appears as a circular stain-filled structure, which projects ~12 nm above the membrane surface and which has an inner and outer diameter of 10–11 nm and 21 nm, respectively[9]. As the isolated MAC extracted from complement-lysed cells[10,11] or assembled from the isolated precursor proteins[12–14], has an ultrastructure that resembles the image of an individual membrane lesion, it has been proposed that each membrane lesion actually constitutes one MAC[11,15].

Membrane damage and cytolysis caused by the MAC has been attributed to lipid bilayer perturbation[16,17] and to transmembrane channel formation[15,18,19]. A critical role for C9 in MAC function and structure is indicated by the following: (1) Although it is not an essential component of immune haemolysis, C9 markedly increases the rate of lysis of C5b–8-bearing erythrocytes[20]. (2) Up to six C9 molecules per C8 molecule were reported to be incorporated into the MAC[21] and subsequently, as many as 12–16 molecules per MAC have been estimated[22]. (3) C9 is essential for the formation of the MAC-induced ultrastructural membrane lesions[13,14]. (4) The size of the MAC-produced membrane pore was reported to be dependent on the concentration of C9[23]. (5) C9 within the membrane-bound MAC was found to be the MAC subunit that was predominantly labelled by membrane-restricted-photoactivatable probes[6,7]. (6) Isolated C9 underwent spontaneous polymerization at 37 °C to form circular polymers resembling the MAC in ultrastructure[24].

We report here that C9, a water-soluble plasma protein, can

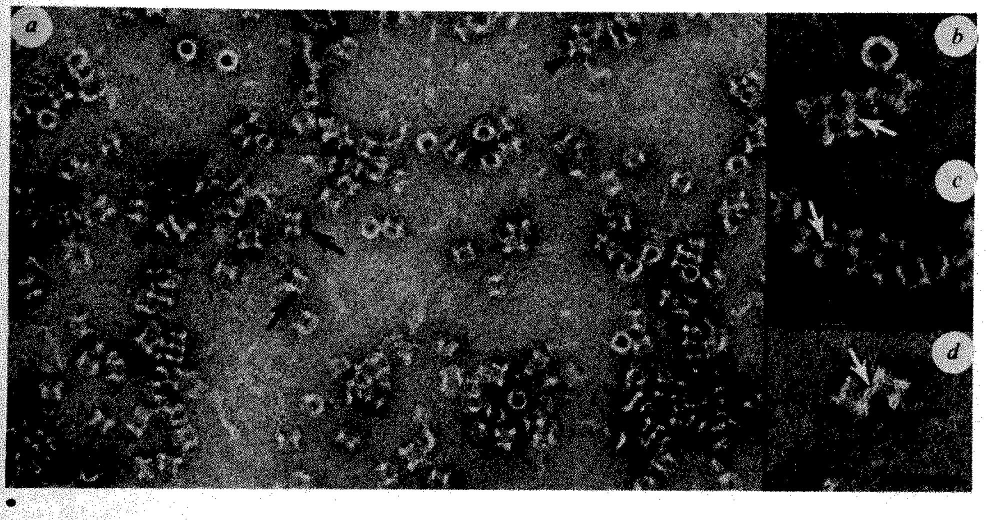

Fig. 1 Ultrastructure of poly C9. C9 was isolated according to Biesecker and Müller-Eberhard[25] and was incubated at a concentration of 5.3 μM in TBS at 37 °C for 64 h. Samples were negatively stained with 2% uranyl formate and examined in a Hitachi model 12A electron microscope at an initial magnification of ×19,550 (*a*). Poly C9 was visualized as a stain-filled tubule with an inner diameter of 11 nm (top views are imaged as rings) and a length of 16 nm (side view, black arrows). The thick-rimmed end comprises a ~3 nm-thick torus with 21 nm outer diameter (black arrowhead). The other end of the tubule terminates in a hydrophobic domain that forms side-by-side aggregates (*b–d*). The white arrows indicate the overlapping areas that presumably represent the hydrophobic segments with a length of 4 nm. Scale bars, 40 nm.

0028-0836/82/310534—05$01.00

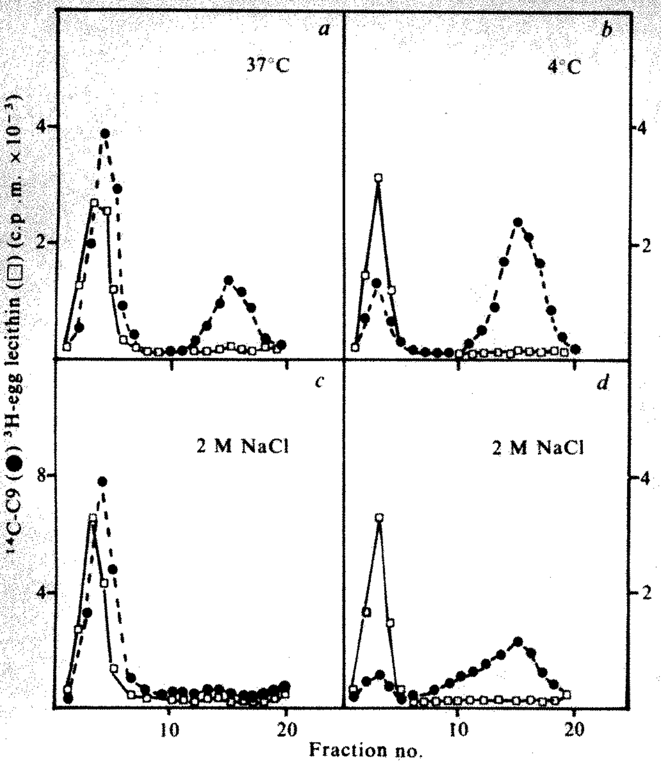

Fig. 2 Interaction of C9 with lipid membranes. Monomeric ^{14}C-labelled[31] C9 (2.6 μM) was incubated in TBS with ^{3}H-labelled egg lecithin vesicles (0.44 μM). Small unilamellar vesicles were prepared by sonication for 1 h as described elsewhere[32]. The samples were then floated through 35% (w/w) sucrose, dissolved in TBS; 1 ml of the sample was made 40% in sucrose, placed on top of a 0.75 ml cushion of 60% sucrose, overlayered with 3 ml of 35% sucrose and 1 ml TBS, then centrifuged to equilibrium at 120,000*g* for 20 h at 4 °C. Fractions (0.25 ml) were collected and analysed for ^{14}C and ^{3}H radioactivity. *a*, C9 was incubated with vesicles at 37 °C for 64 h and most of the C9 underwent flotation together with the vesicles. *b*, C9 was exposed to vesicles at 4 °C for 64 h; only a small fraction of C9 associated with the floating vesicles. *c*, When the vesicle-containing fraction of *a* was again ultracentrifuged in 35% sucrose containing 2 M NaCl, almost all the C9 remained bound to the lipid. *d*, When the corresponding fraction of *b* was treated similarly, most of the C9 dissociated and stayed behind the floating vesicles. The direction of flotation is towards the left.

polymerize and thereby become an integral membrane protein having membranolytic activity and the ultrastructural appearance characteristic of complement-induced membrane lesions.

C9 acquires hydrophobic domains on spontaneous polymerization

Isolated monomeric C9 is a water-soluble protein consisting of a single polypeptide chain with a molecular weight of ~71,000 (ref. 25). It is monodisperse on ultracentrifugal analysis and has a sedimentation coefficient of 4.5S. During incubation for 3 days at 37 °C, isolated monomeric C9 polymerized and assumed the ultrastructural appearance shown in Fig. 1. Views from the top and sides suggest that poly C9 is a 16 nm-long tubule with an internal channel of ~11 nm diameter. One end of the tubule is rimmed by a ~3 nm-thick torus of 11 nm inner and 21 nm outer diameter. Analytical ultracentrifugation of poly C9 showed a polydisperse sedimentation behaviour with sedimentation coefficients in the range 27–250S. Poly C9 aggregated to form arrays in which the tori of adjacent tubules pointed in opposite directions, and in which the smaller ends of the tubules combined side-by-side and overlapped by ~4 nm (Fig. 1*b*,*c*). These overlapping segments presumably constitute the hydrophobic domain of the poly C9 tubule. Poly C9 aggregates dissociated to a 27S species on treatment with detergents, that is, 1% sodium desoxycholate or 0.1 M octylglucoside, indicating hydrophobic interaction between individual poly C9 tubules. In these conditions, poly C9 itself did not dissociate into monomers. The ultrastructure of poly C9 suggests a dodecameric to hexadecameric composition. In view of the molecular weight of monomeric C9, the calculated molecular weight of poly C9 is $0.85–1.14 \times 10^6$, in agreement with preliminary molecular weight determinations.

The amphiphilic properties of poly C9 were tested by studying C9–phospholipid vesicle interaction. In a typical experiment, egg lecithin vesicles were incubated with monomeric C9 for 3 days at 37 °C to effect C9 polymerization. After ultracentrifugation of the protein–lipid mixture in 35% sucrose, most of the poly C9 (60–90%) underwent flotation together with the lipid vesicles (Fig. 2*a*). Incubation of C9 with vesicles at 4 °C did not promote C9 polymerization and resulted in only 10–30% binding of C9 to the vesicles (Fig. 2*b*). The latter protein–lipid interaction was ionic because C9 could be dissociated from the vesicles by 2 M NaCl (Fig. 2*d*). In contrast, the poly C9–lipid interaction at 37 °C was stable on exposure to 2 M NaCl (Fig. 2*c*), suggesting hydrophobic interactions between poly C9 and the hydrocarbon core of the lipid bilayer. The differential binding of C9 at 4 °C and 37 °C cannot be attributed to different physical properties of the egg lecithin vesicles because both temperatures are well above the phase transition. Therefore, the increased affinity of C9 for lipid at 37 °C must be due to C9 polymerization and concomitant acquisition of hydrophobic domains.

Membranolysis by poly C9

The acquisition of hydrophobic sites by polymerizing C9 correlated well with the expression of membranolytic activity (Fig. 3). The rate of appearance of hydrophobic sites on poly C9 was determined by the increase in 8-aminonaphthalene-1-sulphonic acid (ANS) binding. Figure 3*a* shows the increase in ANS fluorescence during incubation of C9 at 46 °C. At this temperature, the rate of C9 polymerization allows continuous monitoring of the reaction by fluorometry. At 20 °C, C9

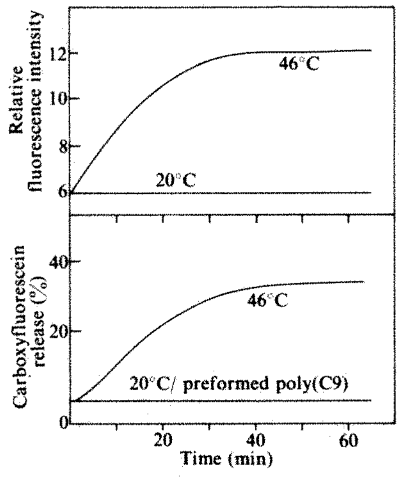

Fig. 3 Correlation of C9 polymerization and lipid vesicle lysis. Carboxyfluorescein (75 mM) was entrapped in large unilamellar egg lecithin vesicles prepared by the reversed-phase evaporation method[26]. C9 (2.6 μM) was incubated with the marker-containing vesicles (20 μM lipid concentration) in TBS in a microcuvette which was placed in a cell compartment with temperature regulation. Membranolysis was continuously monitored by means of the fluorescence increase observed on dilution of the originally self-quenched entrapped carboxyfluorescein[33]. Maximal release of marker was determined after the addition of 0.8% Triton X-100. The extent of lysis was corrected for a small amount of spontaneous marker release. *a*, Rate of acquisition of hydrophobic binding sites by C9, as assessed by ANS binding, which correlates with C9 polymerization[24]. *b*, Rate of marker release at 46 °C. The lines parallel to the abscissa represent controls: lack of C9 polymerization at 20 °C (*a*) and lack of marker release at 20 °C (*b*).

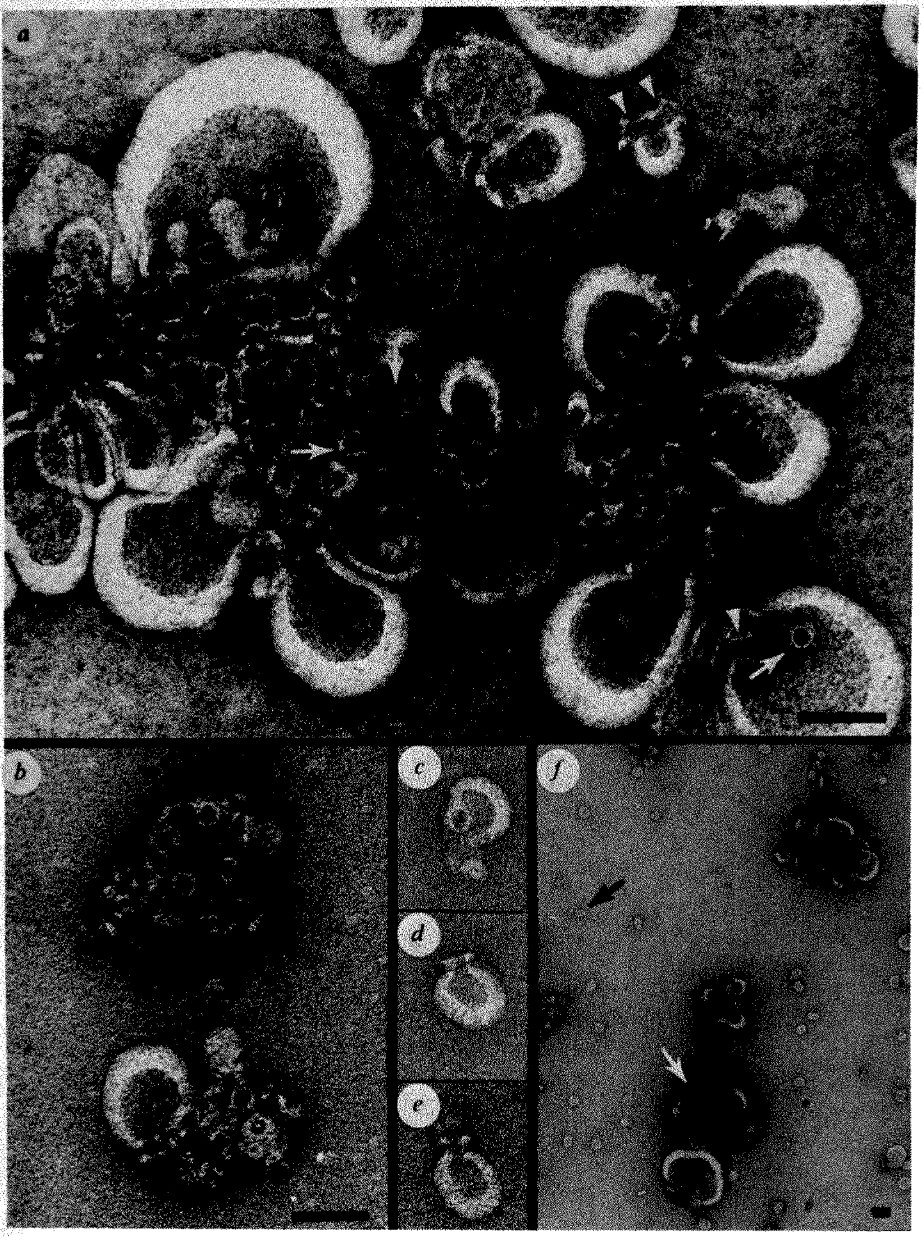

Fig. 4 Ultrastructure of poly C9–vesicle complexes. Poly C9–vesicle complexes were prepared by incubating sonicated and gel-filtered[32] egg lecithin vesicles of 21 nm diameter with monomeric C9 at 37 °C for 64 h. The ratios of C9 monomers per vesicle were: *a*, 6 : 1; *b*, 50 : 1; and *c*, *d*, *f*, 12 : 1. For comparison, a MAC–vesicle complex is shown in *e*. The field of view in *a* shows fused poly C9-vesicle complexes. White arrows indicate top views; white arrowheads, side views of poly C9 attached to bilayer membranes. The inner and outer diameters of the ring structure in top views are 11 nm and 21 nm, respectively; in side views poly C9 projects ~12 nm from the membrane surface. The dimensions of poly C9–vesicle complexes correspond closely to those of MAC–vesicle complexes shown for comparison in *e*. The effects of high C9 multiplicity per vesicle are shown in *b* (50 C9 monomers per vesicle). Multiple poly C9 complexes per vesicle caused bilayer disassembly. *c*, *d* Show single C9 tubules attached to single bilayer vesicles in comparison with a MAC–vesicle complex in *e*. *f*, The fusogenic effect of C9 on vesicles when incubated at a 12 : 1 or lower ratio. The originally small vesicles of ~21 nm (black arrow) fuse to form large vesicles (>100 nm) bearing poly C9 (white arrow). Note also the absence of stain penetration into vesicles lacking poly C9. Scale bars, 50 nm.

remained monomeric and no increase in fluorescence occurred. The membranolytic activity of poly C9 was measured by the release of entrapped carboxyfluorescein from large unilamellar vesicles[26]. C9 polymerization at 46 °C caused vesicle lysis, commencing after a lag period of 5 min, which proceeded at a rate which correlated with the rate of acquisition of ANS binding sites by the protein. After 40 min, 40% of the maximal dye release was observed. This value is only slightly lower than that observed for C9 in the presence of the C5b–8 complex (that is, 55%). C5b–8, however, increased the rate of C9-dependent dye release to the extent that only 2 min were required for maximal release compared with ~40 min for C9 alone. In control experiments, neither C5b–6, C7, C8 nor bovine serum albumin induced membranolysis. Preformed poly C9 added to vesicles expressed no membranolytic activity. Loss of activity may be due to aggregation of poly C9, which probably conceals the hydrophobic domains that are essential for contact with the lipid (Fig. 1). Alternatively, polymerization and insertion into the hydrophobic interior of lipid bilayers may have to occur simultaneously. It is probable that either dimeric or oligomeric C9 initiates the insertion process.

Ultrastructure of poly C9–vesicle complexes

Figure 4 shows electron micrographs of poly C9 attached to egg lecithin vesicles. Poly C9 is visualized as the thin-walled tubule described above for the fluid phase polymer. In profile, it projects ~12 nm from the outer surface of the vesicle membrane, indicating that a 4 nm-long domain is inserted into the lipid bilayer. This value correlates well with the length of the overlapping segments of poly C9 in aggregates of poly C9 (Fig. 1*b*–*d*). The ultrastructure of poly C9, and the presence of stain inside vesicles with bound poly C9, suggest that it forms a transmembrane channel. The fact that poly C9 bound to vesicles resembles the vesicle-bound MAC (Fig. 4*e*) suggests that poly C9 is an integral part of the fully assembled MAC and that it provides the transmembrane channel within the membrane-bound MAC. This interpretation is supported by the results of three-dimensional reconstruction of MAC-bearing vesicles[19], of freeze-fracture studies of MAC-bearing erythrocytes[27] and by studies showing membrane penetration of C9 (ref. 28). In addition to channel formation, poly C9 fuses small, single bilayer vesicles to large vesicles (Fig. 4*f*). Vesicle fusion was observed at an input of <12 C9 monomers per vesicle. An input of 50 C9 monomers per vesicle resulted in complete disruption of the vesicles (Fig. 4*b*), presumably due to the lipid-binding capacity of poly C9, which may be similar to that of the C5b–9 complex[16].

Conformational change on C9 polymerization

Conversion of monomeric C9 to membrane-inserted poly C9 was examined by circular dichroism (CD) spectroscopy. The weak interaction of monomeric C9 with small unilamellar vesicles at 4 °C was not accompanied by a conformational change. In contrast, C9 polymerization and membrane insertion resulted in a decrease in the ellipticity between 210 and 220 nm. Analysis of the spectra by the method of Provencher and Glöckner[29] yielded values of 24% α-helix and 32% β-sheet for monomeric C9 and 22% α-helix and 38% β-sheet for poly C9, indicating an increase in the amount of β-pleated sheet structure.

To determine whether the same conformational change of C9 occurs on MAC formation, C9 and C5b–8 bound to lipid vesicles were mixed at 4 °C and 37 °C at a molar ratio of 12:1. At 4 °C, C9 interacts reversibly with C5b–8 (refs 22, 30) without polymerizing. The circular dichroism (CD) spectrum recorded at 4 °C (Fig. 5*b*) therefore is the sum of the signals of monomeric C9 and C5b–8. When the same mixture was brought to 37 °C, C9 polymerization and MAC formation occurred, accompanied by a change in the CD spectrum similar to that observed during C9 polymerization on vesicles. The two CD difference spectra for poly C9 (poly C9 minus monomeric C9) and for MAC [MAC minus (C5b–8 plus C9)] (Fig. 5*a*,*b* insets) show the same conformational change. The occurrence of a structural change of the C9 monomer on polymerization was also indicated by electron microscopic analysis[24]. In contrast to the globular appearance of monomeric C9, the protomer dimensions of C9 in poly C9 indicated an extended conformation. In addition, comparative immunochemical analysis of poly C9 and MAC showed identical neo-antigenic (conformational) determinants that are specific for poly C9 but which are not detectable in monomeric C9 (ref. 22). These data further indicate that poly C9 constitutes the channel-like structure in the MAC.

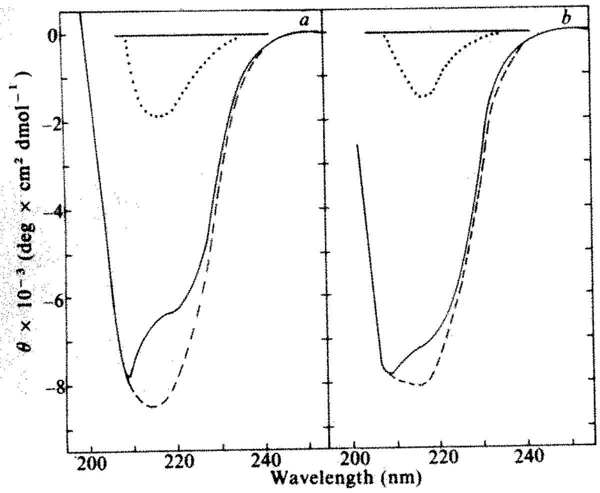

Fig. 5 Far-UV circular dichroism (CD) spectra of vesicle-bound poly C9 and MAC. CD measurements were performed in a Dichrograph III (Jobin Yvon Instruments). The absorbance value of the proteins in TBS at 280 nm was used to calculate their concentrations. The absorbance coefficients used were based on quantitative amino acid analysis and have been published elsewhere[22]. Using a Nicolet model 535 signal averager interfaced to the CD instrument, four individual CD scans were averaged and corrected for the baseline. Results are expressed as the mean residue ellipticity with a mean residue weight of 112. *a*, C9–vesicle complexes were prepared as described in Fig. 2 at a molar ratio of 1:2 poly C9 to vesicle, assuming 12 C9 monomers per poly C9. The solid line represents the CD spectrum of monomeric C9 mixed with vesicles. The broken line shows the spectrum of the same sample after C9 had been polymerized on the vesicle membrane by incubation at 37 °C. Protein concentration, 0.2 mg ml^{-1}. *b*, C5b–6, C7 and C8 (0.22 μM each) were mixed at 30 °C for 15 min with 0.45 μM small unilamellar vesicles, to form vesicle-bound C5b–8. The mixture was cooled on ice and 2.6 μM C9 added. The Cd spectrum was recorded at 4 °C (solid line). The same sample was then warmed to 37 °C for 30 min to allow MAC formation. After re-cooling to 4 °C, the CD spectrum was monitored (broken line). The dotted lines (insets) depict the CD difference spectra of poly C9 minus monomeric C9 (*a*) and of MAC minus (C5b–8 + C9) (*b*). The spectra were calculated by subtracting the solid line spectra from the broken line spectra using a Nicolet data processor. In the case of MAC formation (*b*), it was assumed that the observed change was due only to a secondary structure change in C9 without any contribution by C5b–8. The difference spectrum is therefore normalized and is expressed as mean residue ellipticity of C9.

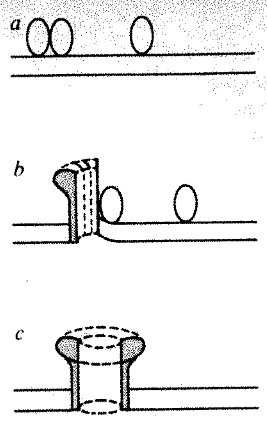

Fig. 6 Hypothetical model for circular polymerization of C9 on lipid membranes. *a*, Reversible binding of monomeric C9 to membranes by ionic interaction. *b*, Polymerization and conformational rearrangements of C9 lead to exposure of previously hidden hydrophobic domains which associate with the hydrophobic core of the lipid bilayer. *c*, Circular polymerization of C9 leads to the formation of a hydrophilic protein channel in the membrane.

Conclusions

The results reported here may be pertinent to the understanding of mechanisms of hydrophilic–amphiphilic transitions of proteins, and may therefore be of relevance to the mechanism of insertion of proteins into lipid bilayers during membrane biosynthesis. Specifically, poly C9 formation is closely related to the cytolytic function of complement and to the ultrastructure of the MAC.

Figure 6 shows a hypothetical model for C9 polymerization on lipid membranes. First, monomeric C9 binds reversibly to the membrane by ionic attraction. Then, multiple electrostatically bound C9 monomers associate and undergo a conformational change involving constrained unfolding of each molecule with exposure of hydrophobic regions that insert themselves into the hydrocarbon core of the lipid bilayer. Additional C9 monomers can then bind to C9 oligomers until the polymerization reaction is terminated by ring closure, one ring containing 12–16 molecules. Our model implies that polymerization of C9 occurs without chemical modification. However, cleavage of a small peptide from C9 by traces of contaminating proteases during the long incubation time has not been excluded.

Exposure of hydrophobic domains in an aqueous environment is thermodynamically unfavourable. The energy for the hydrophilic–amphiphilic transition of C9 is probably derived from the high-affinity C9–C9 interaction during poly C9 formation. Polymerization may cause conformational rearrangement of C9 monomers leading to exposure of hydrophobic domains. Hence, polymerization of C9 may be favoured within a hydrophobic environment, that is, in membranes. The rate of polymerization at 37 °C is highly accelerated by detergents[24]; this effect is of interest as the hydrocarbon core of detergent micelles provides an environment similar to the hydrocarbon core of membranes.

The membranolytic activity of poly C9 is demonstrable with artificial membrane vesicles (Fig. 3). Cytolytic activity of poly C9, however, is not readily apparent. Of the cells tested, only chicken erythrocytes showed a certain degree of susceptibility to lysis by polymerizing C9 (not shown). The inability of polymerizing C9 alone to perturb natural membranes protects host cells against the potential membranolytic activity of C9, and emphasizes the biological role of C5b-8 as C9 receptor and modulator in providing access to the lipid bilayer and promoting C9 polymerization.

There is strong evidence that poly C9 is an integral unit of the MAC: (1) Identical conformational changes occur on polymerization of isolated C9 and on binding of C9 to C5b-8 (Fig. 5). (2) The ultrastructural image of poly C9 and the MAC are very similar (Figs 1, 4). (3) C5b-8 can bind as many as 12-14 C9 molecules in forming the MAC[22]. (4) Identical C9-specific neo-antigens are expressed by poly C9 and the MAC[22]. Therefore, evidence suggests that poly C9 is part of the MAC and forms a transmembrane channel within the MAC assembly. The principle of circular polymerization accompanied by hydrophilic–amphiphilic transition of a soluble precursor may also be valid for cytotoxic effector systems other than complement.

Spontaneous generation of density perturbations in the early Universe

Matt Crawford & David N. Schramm

Astronomy and Astrophysics Center, The University of Chicago,
Chicago, Illinois 60637, USA

A long-standing problem in cosmology has been to understand the origins of density inhomogeneities in the Universe. Calculations involving inhomogeneities have for the most part required the assumption of some initial spectrum of perturbations, which is inserted 'by hand'. We present here a mechanism for the spontaneous creation of density perturbations during the transition in the early Universe from unconfined quark matter to hadronic matter. The subsequent evolution of these perturbations remains a problem for further study.

It is possible that some of these density perturbations, if sufficiently large, may become black holes with masses up to the horizon mass of 10^{30} g, smaller than a solar mass but greater than the mass of 10^{15} g which would evaporate by the Hawking mechanism in the age of the Universe. These black holes would survive to the present and could perhaps be an important component of the dark matter in clusters of galaxies and yet would not be constrained by the upper limit on baryonic mass density from big-bang nucleosynthesis. They would then satisfy the condition[1] that the dark matter in large clusters should be non-baryonic. These black holes would, however, be constrained by the limit on the total mass density derived from the deceleration parameter q_0. Therefore $<10^{-8}$ of all material going through the quark–hadron transition could become black holes.

At the time of transition[2] the age of the Universe is $\simeq 3\times 10^{-6}$ s and, as mentioned before, the horizon mass is far smaller than a solar mass, much less a galactic mass. Thus the existence by itself of the perturbations described here is not sufficient to explain the origin of galaxies. However, it may be that these perturbations can be 'seeds' which could grow through some other mechanisms to larger scales. Press and Vishniac[3] point out that for such growth to be possible, some correlated process is required, such as shocks which produce other shocks. Shock waves to start this process could come from explosions of objects created by these perturbations, or the baryons which form objects around black holes created at the transition. Such shocks could cause perturbation scales to grow as the horizon expands, in a manner similar to the idea proposed by Ostriker and Cowie[4].

We now consider quantitatively how the quark–hadron transition may lead to perturbation growth.[5] In particular, Olive[2] has mentioned that the transition may be a first-order phase transition with a duration comparable to the age of the Universe at the time when the transition occurs. Thus, there is enough time for the perturbations once formed to grow to scales that are some reasonable fraction of the horizon. (Recent unpublished work by Shenker supports the idea of a first-order phase transition for SU_3 with relativistic quarks.)

The physical principle that enables perturbations to form spontaneously and grow comes from the observation of quark–quark interactions in high-energy physics experiments. The experiments show that the Ψ/J- charmonium spectrum[6] and the Υ-bottomonium spectrum[7] are best fitted if the quark–quark interaction potential grows linearly in strength with distance of separation between quarks. Such a dependence is a natural consequence of the non-abelian SU_3 colour gauge theories. This idea of a potential increasing in strength at longer distance is fundamental to the concept of quark confinement and also will stimulate perturbation growth at the phase transition, where quarks combine to make hadrons. If we take, for example, a quark–anti-quark pair out of the quark soup or similarly a triplet of three quarks out of the quark soup to make a meson or baryon, the neighbouring quarks surrounding the site where the hadron has just formed will be able to see the colour charge of quarks further away across the gap where the hadron has formed, as opposed to other directions where colour screening results in a relatively short range interaction, thus there will be unstable growth of perturbations throughout the entire phase transition. However, some saturation in the growth occurs because the strength of the interaction at large distances is sufficiently high that quark–anti-quark pairs are spontaneously produced. The stimulation of the first hadron formation will just be the expansion of the Universe with normal thermal statistical fluctuations.

To investigate this effect, we have run a relativistic n-body stimulation of coloured quarks and antiquarks interacting classically with a two-body potential given by:

$$V(r, C^2) = \begin{cases} 0 & \text{if } C^2 > \frac{8}{3} \text{ and } r > 1.670 \text{ fm} \\ -\frac{1}{2}(C^2 - \frac{8}{3})\, f(r) & \text{otherwise} \end{cases} \tag{1}$$

where C^2 is the combined colour of two particles, assigned in accordance with the Clebsch–Gordon coefficients of SU(3) and

$$f(r) = \begin{cases} \dfrac{6\pi}{33 - 2n_f}\, \dfrac{\hbar c}{r} \left(\log \dfrac{\Lambda r}{\hbar c}\right)^{-1} & r \leqslant 0.132 \text{ fm} \\ (0.620 \text{ GeV fm}^{-1})\text{r} - 1.035 \text{ GeV} & r > 0.132 \text{ fm} \end{cases} \tag{2}$$

Here n_f is the number of quark flavours with mass $\leqslant \hbar c/r$. (Note that we have assumed the potential derived from Ψ and Υ mesons, it is not automatic that this should also apply identically to free quark interactions; however, our conclusions mainly depend on the functional forms.)

The effect of the cutoff in equation (1) is that repulsive forces have limited range while the range of attractive forces between quarks is limited only by the screening effects of nearer quarks.

A quark and an antiquark were deemed to have formed a meson if they were in a colour singlet state and if, in addition, their mutual interaction was at least 10 times greater in absolute value than the interaction of either of them with any other particle. The inclusion of baryon formation was regarded as not worth the added numerical difficulties as the excess of quarks over antiquarks at the time of the transition is approximately 1 part in 10^9 and the bulk of the hadronic matter in the Universe was in mesons rather than baryons at this time.

Taking $\Lambda = 500$ MeV, an initial temperature[2] of 400 MeV, and using the constituent quark masses $M_d = M_u = 300$ MeV, $M_s = 500$ MeV (all heavier quarks being scarce at this temperature), we find a generated perturbation spectrum $\phi(n) \equiv \delta\rho/\rho \approx n^{-\alpha}$ with $\alpha = 0.618 \pm 0.027$. (This is close to the Zeldovich $n^{-2/3}$ spectrum which is favourable[8] to black hole formation.) As we will show below, the amplitude of the fluctuation spectrum produced in our model is too low for very efficient immediate production of black holes. Efficient black hole production would require $\phi(n) \sim 1$ for $n = n_H$, where n_H is the number of particles inside the horizon. The uncertainty in the exponent includes statistical errors and the effects of varying the screening parameters. The screening was varied from run to run so that each quark in the initial state interacted with an average of from 5 to 12 of its nearest neighbours at each time step. If the average number of interactions per quark was more than ~16, the transition no longer took place in this model. The quark masses were not varied. However, it is expected that variations in assumptions about quark masses would have little effect on our conclusions, as their primary effect is to set the initial abundances of quarks due to the fact that the temperature is comparable to the masses.

The transition in our model proceeds by a nucleation process although it differs from vacuum phase transitions in that there is no apparent potential barrier. Our simulations do not show any characteristic 'bubble size' above which the fluctuation spectrum is damped from its power-law behaviour. This indicates that the induced correlations have either unlimited ranges (up to the horizon size) or that the range, if limited, is larger than the size which can be numerically simulated. In the latter case, subsequent rapid growth of perturbations is still a possibility due to the presumably unstable nature of the high-density meson aggregations formed by the transition.

It is reasonable to expect that the radiation participates in the density fluctuations along with the matter, as the clustering of the quarks takes place under the influence of the colour interaction which is stronger than the pressure of the electromagnetic radiation to which the quarks are also coupled. With this supposition we can estimate an upper limit to the direct formation of black holes of mass $\geqslant 10^{15}$ g. (As Carr[8] has emphasized smaller mass black holes lead to unacceptably large amounts of Hawking radiation.) Simply extrapolating the fluctuation spectrum $\phi(n)$ to a number of particles $n_c \approx 3 \times 10^{38}$ corresponding to a mass of 10^{15} g gives an upper limit $\phi(n_c) = 10^{-24\pm1}$ on the fraction of the total mass-energy at the time of the transition which could wind up in black holes of sufficient mass to survive to the present. After the annihilation of matter and anti-matter the mass density due to these black holes would amount to just $10^{-15\pm1}$ times the remaining baryon density. Forming even these black holes requires large compressions. (Note that the initial clustering is not due to traditional Jeans type instabilities but due to the long-range colour force.) Unless the behaviour of meson matter is very favourable to collapse, most black holes formed will be near the horizon mass of $\sim 10^{30}$ g, where the background density is already near the required density for collapse. In any case, we expect the black hole masses to be unaffected by accretion as the total mass gained by a black hole of initial mass M from the time of the quark–hadron transition to the present is $\leqslant 3 \times 10^{-4}\, M^2/10^{30}$ g.

We can show that even with the most generous possible rates of formation the evaporation of small ($< 10^{15}$ g) black holes would not produce γ rays in excess of observational limits. Let the black holes be produced on all scales up to the horizon with the same spectrum as the generated density fluctuations. Then the mass contained in black holes in the mass range $(M, M + \mathrm{d}m)$ is $M^{-\alpha+1}\,\mathrm{d}M$. If $M_{\text{big}}/M_{\text{small}} =$ the ratio of the total mass in black holes of mass 10^{15}–10^{30} g to the total mass in black holes smaller than 10^{15} g, $M_{\text{big}}/M_{\text{small}} = (10^{15})^{-\alpha+2} - 1 = 10^{20.7\pm0.4}$. Thus, if we leave aside problems of the normalization of the black hole spectrum, due to indirect subsequent balck hole formation, the higher mass black holes can contribute a density up to the critical density while the energy density of γ rays from the evaporation of smaller ones will be $\leqslant 10^{-28.5\pm0.4}$ erg cm^{-3}, below the observational value[8] of $\sim 10^{-15.8}$ erg cm^{-3}.

It is interesting to speculate on the subsequent evolution of a critical density ($\Omega \sim 1$) in planetary mass black holes. Because they have no charge they could begin to cluster gravitationally once they become the dominant mass of the Universe which could occur at an order of magnitude higher redshift than recombination. If there were primordial fluctuations, they would get trapped in them and make for example, excellent dark mass halo material. If there were no primordial fluctuations, one might expect a slow statistical cluster growth. These small clusters of black holes could then capture baryons once the baryon decoupled and had a low enough Jeans mass. The black hole cluster centred baryon objects might be the initial seeds for the Ostriker–Cowie scenario. However, if perturbations were built up in this latter manner they always fall within the horizon. Thus there would be no non-zero quadrupole moment to the 3° background. If the present measurements are real[9] then the planetary black holes are still allowable as dark matter but they do not produce galaxies.

We conclude that the quark–hadron transition in the early Universe can produce density fluctuations which might themselves propagate to large scales through some undetermined process, or which could produce black holes with a mass spectrum which allows them to provide the 'missing mass' on any scale. However, to discover whether these black holes can be produced in sufficient numbers to provide the required dark matter will require detailed study of the evolution of the density perturbations in the meson-rich material after the transition.

We thank Craig Hogan, Mike Turner and Keith Olive for valuable discussions. D.N.S. thanks P. B. Price and his colleagues at Berkeley and John Ellis and Alan Guth for stimulating discussions. This work was supported in part by the NSF and by the US Department of Energy at the University of Chicago.

The peculiar variable star R Aquarii and its jet

Minas Kafatos* & Andrew G. Michalitsianos

Laboratory for Astronomy and Solar Physics, NASA Goddard Space Flight Center, Code 685, Greenbelt, Maryland 20771, USA

Outward motion of the nebula associated with the symbiotic variable R Aquarii was suspected by Hubble[1] and confirmed by Baade[2], who estimated its ejection ~600 yr ago. A new feature of the nebulosity near the star appeared between 1970 and 1977 as found by Herbig from direct plates obtained with the 3-metre telescope at Lick Observatory. The 'spike' or 'jet' so-called by Wallerstein and Greenstein[3] appears as a protrusion from the central star. The observational properties of the jet in both the optical and radio are described by Sopka *et al.*[4]. The near UV image obtained in 1980 by Herbig and the VLA radio map[4] are shown combined in Fig. 1. Here we suggest that the jet is the result of supercritical accretion of mass transferred from the cool 387-day period Mira to the hot companion in a highly elliptical orbit. Ancient Japanese astronomical records suggest a nova outburst in AD 930 may be associated with R Aquarii which formed the outer extended nebulosity. The jet may help explain the outbursts of this object as well as the excitation of the R Aquarii nebula.

R. Aquarii undergoes erratic episodes in which the hot compact central ionizing source dominates the integrated visual light. In the 1928–35 outburst the optical spectrum was characterized by a blue continuum and hydrogen P-Cygni profile emission lines which dominated the normally strong absorption spectrum of the cool Mira[5]. Willson *et al*[6]. have studied the visual light curves of the Mira and found that maximum light associated with the 387-day light cycle undergoes unusually deep minima in 1934 and 1978. They suggest that an eclipse of the Mira occurred at these times in which a gas cloud or accretion disk in the system occulted the Mira for ~8.5 yr. Their interpretation suggests an orbital period of ~44 yr. In examining their work we find that the period may actually be ~22 yr, similar to that found by Merrill[7]. In what follows we adopt a 44 yr binary period. Our basic results are not sensitive to the exact value adopted in the 22- to 44-yr orbital period range.

Merrill[7,8] has discussed the spectroscopic properties of R Aquarii from 1920 to 1950, and from velocity measurements finds that the orbital eccentricity $e = 0.5$. Here, we suspect that the orbit is also highly elliptical, but disagree with the notion that the 'eclipse' or suppression of Mira light took place at apoastron as required by Willson *et al.*[6]. Examining the radial velocity curve of Merrill[7], we note that the 1934 eclipse may not have occurred near apoastron. It we take a binary period of 44 yr, apoastron would have occurred in 1920, and the eclipse of 1934 would more closely coincide with periastron. We believe that the appearance of the jet (sometime between 1970 and 1977) which coincided nearly with the eclipse or suppression of Mira light, provides a theoretical basis for believing that this event occurred at periastron.

If the Mira and secondary are in a highly elliptical orbit, near periastron the Mira envelope becomes extended due to the close proximity of the secondary at this particular orbital phase. Mass transfer to the companion occurs forming a spatially thick accretion disk ar supercritical accretion rates, which is accompanied by the formation of a jet, possibly driven by radiation pressure[9]. A few years later after the stars separate sufficiently the Mira relaxes to its previous undisturbed state. It is possible of course, for quasi-periodic outbursts to occur separated by the thermal time scale of the red giant envelope (see below) with no eccentricity in the binary model.

We have carried out theoretical analysis that supports this model Bath and Pringle[10] have made time-dependent accretion disk calculations in symbiotic binaries with separations of the primary and secondary $\sim 10^{13}$ cm. In their model the accretion disk forms around a main sequence star, or around a smaller star with effective photospheric radius $\sim 1R_\odot$. Even though the orbital separation of the stars is believed larger by one order of magnitude than that considered by Bath and Pringle[10], the high eccentricity[5,7], assumed here may allow accretion to occur at particular phases of the orbit, that is, at periastron. If the separation of the stars at periastron is ~1–2 times the radius of the Mira[11], supercritical mass transfer occurs through the critical Roche lobe, characterizing the system by episodic accretion events every 44 yr.

From the 387-day light cycle of the Mira (hereafter referred to with subscript '1', '2' denoting the companion) we find $R_1 \sim 250\text{–}300 R_\odot$ (refs 12, 13). For $M_1 \sim 1.5 M_\odot$ (ref. 12) and $M_2 \sim M_\odot$ and a binary period of 44 yr, we find that the semi-major axis of the ellipse $a \sim 2.5 \times 10^{14}$ cm. This value is in close agreement with that obtained by Merrill[7]. In a purely circular orbit the Mira would always fail to fill its Roche lobe by a factor of 5–7. In a highly elliptical orbit, however, episodic mass transfer could occur around periastron. Farther away from periastron the secondary would only accrete material expelled from the Mira in a stellar wind at much lower rates. Using the criterion for Roche lobe formation of Haynes *et al.*[11] we find that the eccentricity of the orbit is in the range $0.84 \lesssim e \lesssim 0.92$ if $R_1 \sim 2 \times 10^{13}$ cm and the semi-major axis is $a \sim 2.5 \times 10^{14}$ cm.

For a main sequence secondary the critical accretion rate is expressed as $M_C = 1.1 \times 10^{-3}\ (R_2/R_\odot)\ M_\odot\,\text{yr}^{-1}$, while for a white dwarf it is $M_C = 1.53 \times 10^{-5}\ (R_2/10^9\ \text{cm})\ M_\odot\,\text{yr}^{-1}$. Bath and Pringle[10] have shown that it is difficult for a white dwarf accreting at sub-critical rates to dominate the M giant optical continuum. It is possible, of course, that the secondary is a white dwarf or hot subdwarf with an effective photosphere ($\tau \sim 1$) at $r \sim 1R_\odot$. The accretion disk would have to be extended and cool in its outer regions if substantial eclipses of the Mira are to occur. If the eclipse occurs at or near apoastron as favoured by Willson *et al.*[6], then for $e = 0.85$, $M_1 + M_2 = 2.5\ M_\odot$ and for a 44 yr period, the minimum radius of the occulting disk R_d (for a line-of-sight to Earth along the semi-major axis of the ellipse) is $\sim 2R_1$. The value is essentially the same if different values of stellar masses are considered. We find that the visible light brightness of the disk should be not more than ~1/5 that of the Mira, and it should be spatially thick ($h/r \gtrsim \frac{1}{2}$). The disk temperature in the outer regions should then be appreciably less than the effective temperature of the Mira, say ~2,800 K (ref. 12). We find that $T_d \sim 2{,}300$ K in the outer regions of the disk, resulting in a disk that would be brighter than the Mira in the 1–3 μm wavelength region. In any case, if $R_d \gtrsim 2R_1$ at apoastron, it would indicate that the gravitational field of the secondary would have to be substantially stronger than that of the Mira to maintain such large disk dimensions

at maximum separation. Moreover, as the two stars approach each other the collision of such a substantial disk with the outer atmosphere of the Mira would likely cause a noticeable brightening in 1957-which was not seen-and which would occur again in the year 2000. Additionally, the large disk model does not explain the 1935 outburst which R Aquarii underwent.

Instead, we believe that the disk around the unseen companion is extended ($R_d \sim 1$–2×10^{13} cm), but not as large as $2R_1$ and achieves its largest extent at periastron. More moderate dimensions for the disk would be more consistent with a mass $\sim 1 M_\odot$ expected for a white dwarf, hot subdwarf or main sequence type companion. The outer regions of the disk in this case would have temperatures $\sim$3,000 K, and would be moderately thick, $h/r \sim v_s/v_K \sim 0.25$ (refs. 14–16), where v_K is the keplerian velocity, v_s the sound speed and h the semi-thickness of the disk[14]. The drift time scale of the disk is $t_r = r/v_r$, where the drift velocity $v_r = \alpha[v_s^2/v_K]$, and α is the usual viscosity parameter[14]. We assume following Bath and Pringle[10] that the α-viscosity model holds. For values of $\alpha \sim 0.1$–1.0 expected for symbiotics[10], we find that $t_r \sim 1.7$–17 yr. At periastron the two stars remain close, say within a few R_1, for ~ 1 yr. The jet forms and persists for a comparable period of time. As the two stars recede from each other the disk dissipates over time scales of the order ot t_r. We estimate that material with a total mass $\gtrsim 10^{-3} M_\odot$ is ejected in the form of a jet if the companion is a quasi-main sequence type star, and $\gtrsim 10^{-5} M_\odot$ if the companion is a white dwarf. The orbit will decay over time scales $t_e \equiv |e/\langle\dot{e}\rangle|$, $t_a \equiv |a/\langle\dot{a}\rangle|$, where $\langle\dot{e}\rangle$ and $\langle\dot{a}\rangle$ are the orbit average rates which can be computed from Alexander, Chau and Henriksen[17]. During quiescent phases away from periastron, and assuming an orbit average lass loss rate for the Mira $\langle\dot{M}\rangle \sim 2\times10^{-5} M_\odot\,\mathrm{yr}^{-1}$ (main sequence type companion), or $\sim 10^{-6} M_\odot\,\mathrm{yr}^{-1}$ (white dwarf companion), we find that the semi-major axis of the ellipse diminishes over time scales $t_a \sim 1.7\times10^5$ yr to 3.4×10^6 yr, respectively. The quantity $\langle\dot{M}\rangle$ is defined as $[\dot{M}_C \times 1\,\mathrm{yr} + \dot{M}_W \times 43\,\mathrm{yr}]/44$, where $\dot{M}_W \sim 10^{-6} M_\odot\,\mathrm{yr}^{-1}$ is the quiescent Mira mass loss rate that occurs well away from periastron. The orbit actually becomes more eccentric over timescales longer than t_a. In any case, if we impose the requirement that during successive episodic mass transfer events between primary and secondary the Mira retains essentially most of its envelope[18] ($M_{env} \sim 0.8\,\dot{M}_\odot$), then the system cannot be older than $M_{env}/\langle\dot{M}\rangle$, or 4×10^4 yr for a main sequence type companion, and 8×10^5 yr for a white dwarf.

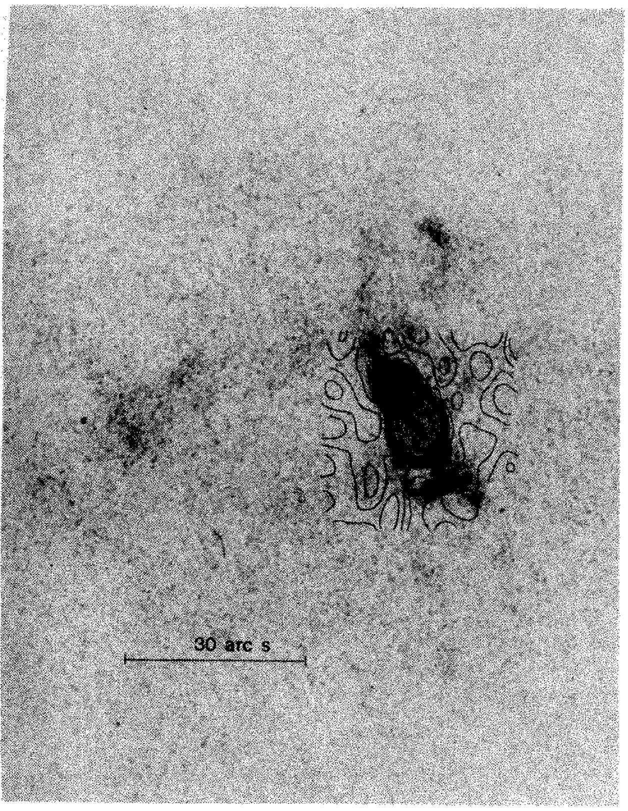

Fig. 1 Optical image of R Aquarii obtained in the near-UV with the 3-m telescope at Lick Observatory (courtesy George Herbig) in October 1980, shown combined with a Very Large Array radio map at 6-cm obtained by Sopka *et al.* on 5 November 1981. The protruding jet features extending from the central star was first noticed by Wallerstein and Greenstein[3] in 1977, and appears to have grown in brilliance over the past several years.

The Mira envelope will relax over thermal (Kelvin–Helmholtz) time scales. We find for typical Mira parameters $L_1 \sim 4\times10^3 L_\odot$, $M_1 \sim 1.5 M_\odot$ and $R_1 \sim 2\times10^{13}$ cm, that $t_{th} \sim 20$ yr. This rough estimate is in agreement with the thermal time scales in the envelopes of the Mira models of Wood[19], which are $\sim$1–10 yr. We also note that some material outside the disk will eventually rain back on the Mira over the free-fall time scale $t_{ff} \sim 0.3$–30 yr, for densities in the outer regions of the disk that are in the range 10^{15}–10^{13} cm^{-3} (main sequence or white dwarf companions, respectively). It is curious that all these time scales are in the range comparable with the 8.5-yr eclipse[6] duration. As such, this phase may not represent an eclipse at periastron (it would last only $\sim$1 yr), but would in fact be the characteristic dynamical time scale required by the Mira to recover to its pre-periastron, quiescent state. Although no detailed calculations of such a complicated system as R Aquarii exist at present to check this hypothesis of disk and jet formation, we believe the overall properties of the system support this model, namely: (1) the brightening of the secondary and the appearance of P-Cygni profiles in 1928 through 1935, indicating mass loss and mass accretion forming a disk; (2) the appearance of the jet between 1970 and 1977 occurred close to the time of periastron predicted in our model. A test of our model can be provided by radial velocity measurements of R Aquarii in the next 10–20 yr to determine the orbital characeristics, and check whether the eclipse of 1978 took place near periastron.

The question whether the secondary is a main sequence star, hot subdwarf or white dwarf has not been conclusively resolved. Important clues concerning its exact nature can be obtained from UV and optical observations of the nebula. We find that the inner nebula responsible for the UV emission lines and UV continuum observed has a radius $\sim 2.5\times10^{14}$ cm, and electron density $n_e \sim 5\times10^6$ cm^{-3} (ref. 21). If the hot subdwarf photoionizes this nebula, thus accounting for the line emission observed in the UV and in the optical, the temperature of the secondary would have to be less than $T_{eff} = 65{,}000$ K in order to explain the weakness or absence of the He II λ1640A line[20]. Accordingly, such a star would be located in the lower part of the *H–R* diagram, generally occupied by central stars of planetary nebulae[21]. Temperatures near 60,000 K are also favoured by Kaler[22]. Such a star would photoionize the inner, higher density nebula, but lacks a sufficient flux to photoionize the entire extended nebulosity.

The extended nebula is still expanding with an average velocity 50–100 km s^{-1} (ref. 1). From the electron densities derived by Wallerstein and Greenstein[3] for the nebula, and using a filling factor value of 0.1, we find an average electron density $\langle n_e\rangle \sim 10^4$ cm^{-3}. The mass of the nebula is $\sim 0.2 M_\odot$ and its kinetic energy $> 2\times10^{46}$ erg. We note that typical nova light output is in the range 10^{44}–10^{45} erg (ref. 24), while for slow-novae such as RR Tel and RT Ser, that resemble more R Aquarii, the output is of the order of 10^{45} erg. The R Aquarii nebula radiates more than 5×10^{44} erg yr^{-1} in the Balmer and Lyman continua and emission lines. The corresponding cooling time scale of the nebula is estimated to be $\sim$2 yr. The question arises naturally, what has been powering this extended nebulosity for the past 600 yr (ref. 1). Photoionization is unlikely because it would require a secondary much brighter than the Mira, which would have to radiate in excess of the Eddington limit for a $1 M_\odot$ star. The luminosity of the secondary was found to be $\gtrsim 3\times10^{38}$ erg s^{-1} using the Stromgren relation with a root-mean-square electron density $\langle n_e^2\rangle^{1/2}\sim3\times10^4$ cm^{-3}.

Alternatively, from purely energetic arguments, the jet could be the source of excitation. Taking a minimum size for the jet feature of 7 arc s (ref. 4), that corresponds to a linear size of $\sim2\times10^{16}$ cm (at a distance 200 pc)[4], and assuming it travelled since 1970, we find an average jet velocity of 700 km s^{-1}. If the mass of the jet is $\sim10^{-3}M_\odot$, then its kinetic energy would be $\sim5\times10^{45}$ erg, in reasonable agreement with estimates for radiation cooling given above. However, most of the material in the extended nebula that surrounds R Aquarii is confined to rings, generally perpendicular to the axis of the jet. Morphologically, this structure argues for the nebula being formed in a single explosive event hundreds of years ago. If formed in an explosion, the ejection which created the present nebula is possibly reflected in the composition of the nebular dust grains, which appear chemically distinct from the material in the interstellar medium[24]. Moreover, the richness of the R Aquarii nebula in He and particularly N (ref. 3) is in agreement with models of recurrent novae[25] and further argues in favour of the nebula having been formed in a single nova-type event.

The present expansion rate of the nebula of 50–100 km s^{-1} and angular extent of ~1 arc min argues for an outburst ~1,100–550 yr ago. We find that only one recorded nova outburst during historical times in the general vicinity (within 10° × 10° box, the uncertainty of ancient records) of R Aquarius is found in ancient oriental astronomical records[26,27]. Specifically, the outburst of AD930 is described as a "guest star entering Yülin" in Japanese astronomical records, for which Yülin is a faint ancient Chinese asterism in Aquarius. The term 'entering' can mean at the edge or periphery (D. H. Clark, personal communication). The approximate coordinates of the guest star of AD 930 are RA ~ 23 h, Dec. ~ −20°, within 10° of R Aquarii, and near the edge of Yülin[27]. A nova outburst would have been discovered and recorded in the Oriental chronicles if its magnitude at maximum was ~2 mag. (ref. 28). In our Galaxy, the frequency of nova outbursts brighter than 2 mag. recorded in the past 100 yr is at a rate ~9 novae per century[23]. The galactic distribution of novae is also known for recent novae[23] and for ancient sightings[26–28]. The probability, therefore, of finding a random nova (different from R Aquarii) within 10° × 10° of this object (with $b = 70.32°$) is small, only ~0.02 for the past 1,000 yr.

From the duration of the outburst of AD930 of a couple of months, adopting a maximum light $m_V\sim2$ mag., we find that if the effective temperature of the hot component during the outburst was in the range 10^4 to 5×10^4 K, then the total light output of the nova is estimated to be $\sim10^{45}$–10^{47} erg. Based on these rough estimates the total energy could account for the kinetic energy presently estimated for the nebula. If correct, R Aquarii would be the first object related to slow-novae and recurrent novae whose outburst was recorded in ancient astronomical records.

The very interesting star R Aquarii has provided us with a number of recent surprises: a jet in the only star besides SS433, the existence of a plausible accretion disk that likely forms at supercritical accretion rates, and a possible ancient Japanese sighting of the initial outburst that produced the nebula. It is obvious this star should be followed carefully in the next 10–20 yr, particularly the radial velocity displacements of emission lines which can provide an indication of the orbit characteristics. Moreover, because of its relatively close proximity of ~200 pc, it may just be possible to spatially resolve an accretion disk around the hot component in the system with Space Telescope.

Other galactic objects associated with jet activity such as SS 433 for example[29] are much further than R Aquarii. Similarly, extragalactic objects[30] are far too distant. R Aquarii offers a much better opportunity to study the formation of jets in suspected accreting systems, and affords us a means of possibly checking directly the physics of accretion disk formation and jet activity.

It is curious that jets tend to form in such widely disparate astrophysical sites as the nuclei of active galaxies[30], in a neutron star or black hole in objects such as SS 433 (ref. 29), and here in hot subdwarfs or main sequence-like companions that accrete. Surely this implies that jet formation is quite a general phenomenon occurring in a variety of astronomical objects.

Magnetostrictive control of coercive force in multidomain magnetite

J. P. Hodych

Department of Earth Sciences, Memorial University of
Newfoundland, St John's, Newfoundland, Canada A1B 3X7

Although the natural remanent magnetization of terrestrial igneous rock is often due to multidomain grains of magnetite or titanomagnetite, it is not certain what controls the coercivity of the multidomain grains and hence the stability of their remanence[1]. Even the related but simpler problem of what controls the bulk coercive force H_c of multidomain magnetite is still not solved. I consider this simpler problem here by noting[2,3] that the coercive force of multidomain magnetite powders[4] varies with low temperature approximately in proportion to the magnetostriction[5] coefficient λ. I find the same approximate proportionality between H_c and λ on cooling six igneous rocks bearing multidomain magnetite. Hence, the coercive force of these powders and rocks seems mainly to be magnetostrictively controlled–presumably through internal stresses. This is even true of the three rocks with high enough H_c (~150 Oe) to be classed as pseudo-single-domain, including two with the fine magnetite–ilmenite intergrowths often observed in terrestrial igneous rocks with stable remanence[6].

There have been several suggestions as to what controls the coercive force of multidomain magnetite. If internal stresses mainly control H_c as suggested for titanomagnetite by Syono[7], the temperature variation of H_c should be given[8] by $H_c \propto G\lambda/J_s$ where G is the shear modulus and J_s is the saturation magnetization. If dislocations impeding domain wall motion mainly control H_c as favoured by Stacey and Wise[9], the temperature variation of H_c should lie[8] between $H_c \propto G\lambda/J_s(K_1)^{1/2}$ and $H_c \propto G\lambda/J_s(K_1)^{1/4}$ where K_1 is the magnetocrystalline anisotropy

0028-0836/82/310542—03$01.00

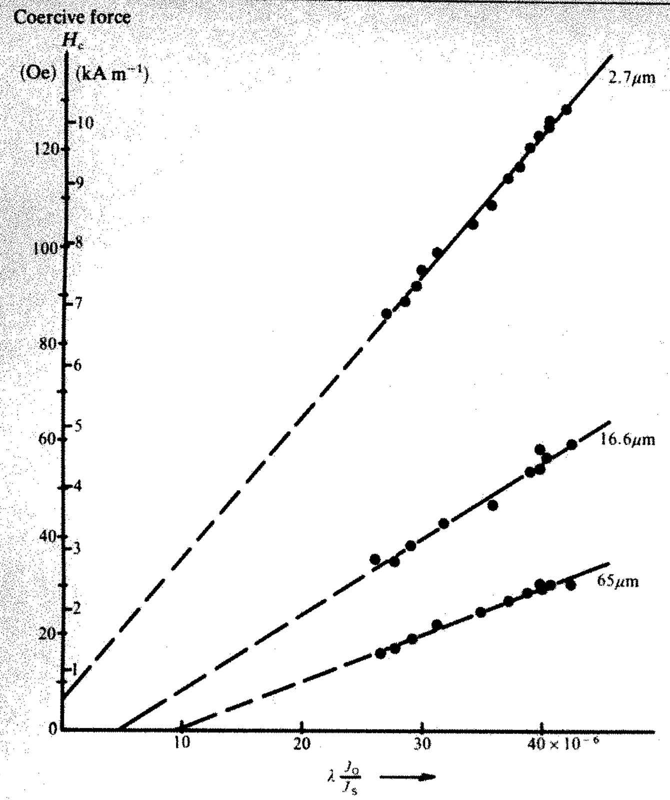

Fig. 1 Coercive force H_c of three grain sizes of crushed natural magnetite measured between ~300 and ~130 K by Morrish and Watt[4] plotted against the corresponding $\lambda(J_o/J_s)$. The polycrystalline magnetostriction coefficient[5] is used for λ. The ratio J_o/J_s of saturation magnetization at 0 K to saturation magnetization at the measurement temperature varies little[14] compared with λ.

coefficient. The possible importance of internal stresses or dislocations to H_c is supported by the observation[10,11] that annealing can substantially reduce H_c of multidomain magnetite. If inclusions mainly control H_c as favoured by Day *et al.*[12] to explain why H_c of their coarse synthetic titanomagnetites does not vary greatly with titanium content, then the temperature variation of H_c should be given[13] approximately by $H_c \propto K_1/J_s$.

It may be possible to decide which of the suggested controls on H_c dominates in a given sample by observing how H_c varies with low temperature. The variation of J_s, K_1, and λ with low temperature is known[5,7,14]. Although the variation of G with low temperature is unknown, it can probably be neglected since G only changes by ~8% between 20 and 255 °C for magnetite[15].

Morrish and Watt[4] measured H_c as a function of low temperature for three grain sizes of multidomain magnetite powder. They concluded that most of the thermal variation of H_c is controlled by K_1 because H_c is a minimum when $K_1 = 0$ (at 130 K). However, H_c is only reduced by 45% or less of its room temperature value when $K_1 = 0$. Furthermore, I find[2,3] that their values of H_c vary approximately in proportion to λ not K_1 from ~300 to ~130 K. Hence, λ rather than K_1 seems mainly to control H_c.

Figure 1 shows the measurements of Morrish and Watt[4] for H_c from ~300 to ~130 K plotted against the corresponding $\lambda(J_o/J_s)$ where J_o is J_s at 0 K. The thermal variation of the polycrystalline $\lambda = 0.4\lambda_{100} + 0.6\lambda_{111}$ was calculated from the smoothed curves of Bickford *et al.*[5] for λ_{100} and λ_{111} versus low temperature. The thermal variation of J_s is comparatively small[14]. For all three grain sizes of crushed unannealed natural magnetite, H_c seems to vary as a linear function of $\lambda(J_o/J_s)$ as expected if H_c is mainly controlled by λ through internal stresses. The line for 2.7-μm grains passes above the origin perhaps because a small fraction of H_c is magnetostatically controlled. The lines for 16.6- and 65-μm grains pass below the origin perhaps because a small fraction of H_c is controlled by K_1 through inclusions. Dislocations impeding domain wall motion do not appear to be the main control on H_c as there is no linear relation between H_c and $\lambda/J_s(K_1)^{1/2}$ or $\lambda/J_s(K_1)^{1/4}$ using K_1 versus low temperature reported by Syono[7].

To test whether magnetostrictive control of H_c is common in rocks bearing multidomain magnetite, the six rocks of Table 1 were studied. Most of the magnetite in each rock is likely multidomain since the ratio j_R/j_s of saturation remanence to saturation magnetization (estimated from 1,200 Oe hysteresis loops) decreases roughly in proportion to H_c on cooling[3].

Figure 2 shows H_c of the six rocks as a function of low temperature. Most of the samples show a minimum in H_c near 130 K followed by an increase in H_c at lower temperatures as expected from the large increase in magnetocrystalline anisotropy accompanying magnetite's cubic to orthorhombic transition below ~120 K. For the two diabases, the minimum in H_c is shifted to lower temperature perhaps due to a little titanium in the magnetite.

Figure 3 shows that for all six rocks, H_c seems to be a linear function of $\lambda(J_o/J_s)$ from near room temperature to ~130 K as expected if H_c is mainly magnetostrictively controlled through internal stresses. The lines for the Shelburne diabase, the peridotite and the basalt pass above the origin perhaps

Table 1 Properties of six igneous rocks containing multidomain magnetite

Rock type	Locality	H_c* (Oe)	j_R/j_s†	Curie point ±7 (°C)
Diabase	Palisades Sill, New York	165	0.23	573
Diabase	Shelburne dyke, Nova Scotia	149	0.22	590
Serpentinized peridotite	Table Mountain, Newfoundland	149	0.30	599
Basalt	India	52	0.08	597
Diorite	Lake Superior	23	0.04	591
Metabasalt	Tweed, Ontario	8	0.02	591

* Coercive force in 1,200 Oe cycles near room temperature.

† Ratio of saturation remanence to saturation magnetization in 1,200 Oe cycles near room temperature.

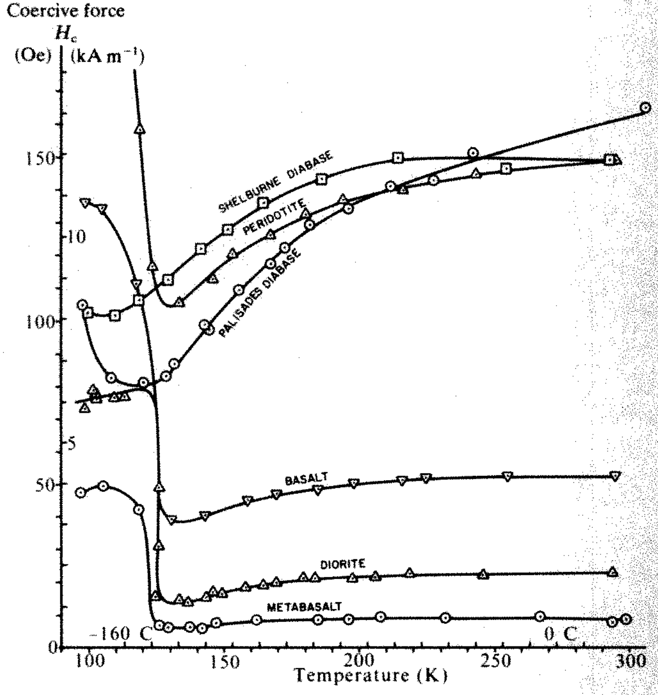

Fig. 2 Coercive force H_c of the six magnetite-bearing rocks of Table 1 measured as a function of low temperature. See ref. 3 for experimental details. For a given sample, the relative error in H_c should be ~±2 Oe but may be greater near room temperature and below 130 K.

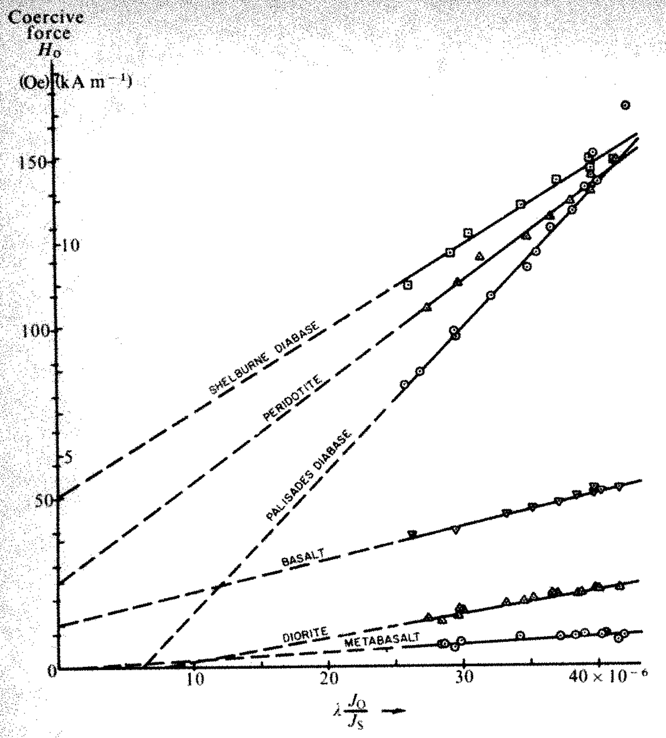

Fig. 3 Coercive force H_c of the six magnetite-bearing rocks of Table 1 measured between ~300 and ~130 K plotted against the corresponding $\lambda\,(J_o/J_s)$ as in Fig. 1.

because a fraction of H_c is magnetostatically controlled. The lines for the Palisades diabase and the diorite pass below the origin perhaps because a fraction of H_c is controlled by K_1 through inclusions. (In the case of the Palisades diabase, the measurements at 300 and 243 K were not included in calculating the least-squares fit line.)

Thus, magnetostrictive control of H_c, probably through internal stresses, does seem common in multidomain magnetite and in rocks bearing it. This even seems true of the upper part of the pseudo-single-domain grain size range judging from the 2.7-μm magnetite and from the peridotite and two diabases with $H_c \sim 150$ Oe and $j_R/j_s \sim 0.2$. Note that the two diabases contain magnetite finely intergrown with ilmenite lamellae in what were originally titanomagnetite grains—a common feature of terrestrial igneous rocks with stable remanence[6].

Magnetostrictive control of H_c may also be common in natural multidomain titanomagnetite with a mole fraction $x = 0.6$ of ulvospinel. I find that H_c increases in proportion to λ on cooling deep-sea basalts containing such grains[3,16]. The same could be true for x between 0 (pure magnetite) and 0.6 since the ratio λ/K_1 for these compositions does not fall much below that of pure magnetite[7].

This research was aided by a grant from the Natural Sciences and Engineering Research Council of Canada and was reported at the International Association of Geomagnetism and Aeronomy assembly in Edinburgh in August 1981[2].

Langmuir–Blodgett films of long-chain amines

George L. Gaines Jr

General Electric Corporate Research and Development,
Schenectady, New York 12301, USA

Widespread interest has developed in the potentialities of molecular films built up on solids by the Langmuir–Blodgett (L–B) technique of sequential transfer of monomolecular layers from a water surface[1,2]. For certain purposes, the fatty acid soaps which are the classical, and most extensively studied, constituents of L–B films, may be unusable. For example, it may be desired to incorporate acid-sensitive molecules, or the presence of heavy-metal ions such as barium or cadmium, which are required to produce the most stable soap layers, may be undesirable. These problems may be overcome in some instances by the use of fatty alcohols or esters, but multilayers of these substances are generally less stable (especially with respect to thermal disruption or vaporization) than those of the heavy-metal soaps. I now report methods for the facile formation of L–B layers of long-chain amine salts which offer comparable, as well as complementary, advantages compared with soap films.

Early studies of long-chain amine monolayers have been reviewed elsewhere[3], while more recent studies[4,5] have provided further information on counter-ion selectivities at low *p*H. *n*-Alkyl amines with chains of 18 or fewer carbon atoms form expanded monolayers, and dissolve relatively rapidly, when they are spread on acidic subphases at room temperature. The addition of strongly bound multivalent counter-ions, such as sulphate[3] or hydrogen phosphate[6], can reduce this tendency. Over a relatively narrow *p*H range, it has been found that facile L–B film deposition of octadecylamine can be carried out in the presence of such anions[6].

With *n*-docosylamine, however, condensed monolayers are formed in a wide range of conditions (Fig. 1). After a few minutes for equilibration with the atmosphere (*vide infra*), the surface pressure–area isotherms are reversible without hysteresis, and the films are stable, showing negligible changes of area when maintained at pressures up to at least 30 dyn cm^{-1}. Especially at *p*H < 7 and room temperature, their monolayers are readily and quickly built into multilayers of excellent optical uniformity by the usual L–B technique. At high *p*H (10^{-3} M NaOH) in air, the layers emerge with an entrapped solution layer and this must be allowed to drain and dry before reimmersion. If this is done, good multilayers can also be obtained although the process is slow. (The same is true for octadecylamine spread on alkaline solutions where a condensed monolayer is formed[6].)

Amines in contact with alkaline solutions form carbamates very readily by reaction with atmospheric carbon dioxide[7]. The facility with which this reaction occurs had not been generally appreciated, and it undoubtedly accounts for many of the peculiarities noted in early studies of amine monolayers[3]. Direct evidence of carbamate formation in spread monolayers can be easily obtained. A monolayer of octadecylamine (melting point 53–54 °C) was spread on 10^{-3} M NaOH and exposed to room air for 10 min, then collapsed and skimmed from the surface. The skim was rinsed with water and dried in vacuum; its melting point was found to be 75–78 °C, identical to that observed for a sample of the carbamate obtained by passing dry CO_2 into an ethanol solution of octadecylamine. IR spectra (Fig. 2) also demonstrate the presence of carbamate in multilayers built from amine monolayers on alkaline subphases in air, as well as incorporated sulphate counter-ions in L–B films formed at low *p*H. Carbamates are not stable in neutral or only slightly basic solutions[7], and the spectrum of a film built up in this *p*H range (Fig. 2, curve *b*) shows reduced levels of both sulphate and carbamate; further study is required, however, to decide

0028–0836/82/310544—02$01.00

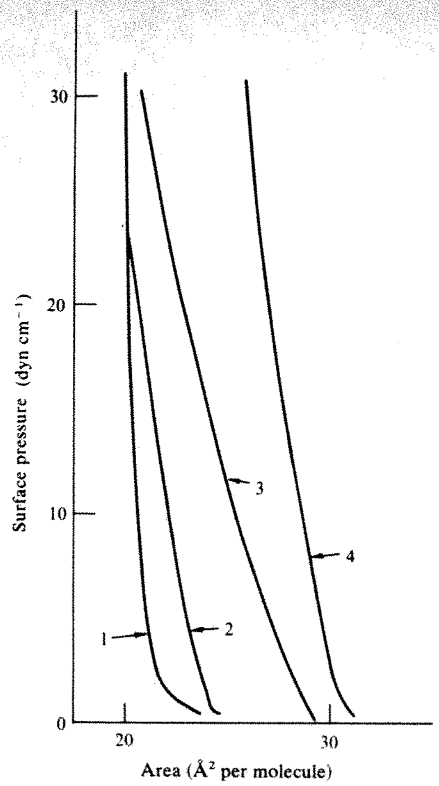

Fig. 1 Surface pressure–area isotherms for *n*-docosylamine in air at 25 °C. Subphase 10^{-3} M NaOH (curve 1) or 0.05 M $(NH_4)_2SO_4$, *p*H 8.3 (curve 2), *p*H 7.5 (curve 3), *p*H $<$ 6.0 (curve 4).

whether these in fact contain free amine. It has also been found that treatment of the carbamate-containing films with sulphate solutions, or sulphate-containing films with NaOH, after they have been built up, can lead to at least partial interconversion of these species as judged by IR spectra, with no significant effect on their visual optical properties (clarity or interference colours).

Multilayers built from 10^{-3} M NaOH exhibit substantial optical changes when heated above 60 °C, while the films formed from sulphate solutions at *p*H $<$ 6 show no detectable changes to at least 100 °C. A 40-layer film deposited on chromium from 0.05 M $(NH_4)_2SO_4$, *p*H 5.6, was baked at 130 °C for 1 h; after cooling, it was found to have developed a hazy appearance, although the interference colours in reflected white light (at either normal or grazing incidence) were unchanged.

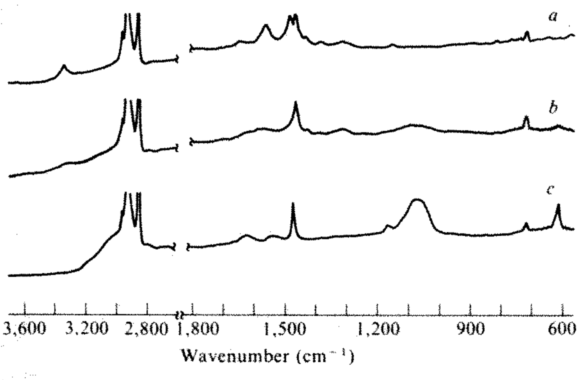

Fig. 2 Transmission IR spectra of 60-layer L–B films of *n*-docosylamine (on Ge plates) built in air from: *a*, 10^{-3} M NaOH; *b*, 0.05 M $(NH_4)_2SO_4$, *p*H 8.7; and *c*, 0.05 M $(NH_4)_2SO_4$, *p*H 5.5. Bands at 617 and 1,080 cm^{-1} are characteristic of sulphate ion; those at 1,570 and 3,340 cm^{-1} are associated with carbamate[11]. The relative intensities of the CH_2 bands at 2,855 and 2,920 cm^{-1} are consistent with the relative molecular packing inferred from the pressure–area curves of Fig. 1.

Multilayers of amines and their salts clearly possess several characteristics analogous to those of fatty acids and their soaps. The degree of counter-ion incorporation (which can affect deposition conditions as well as the properties of the built-up layers) will depend on the composition (especially *p*H) of the subphase from which they are built. Although no extensive results are yet available, I have found that some films built at *p*H 7–8, where only partial salt formation may occur, exhibit interference colour changes after being immersed in solvents which are reminiscent of the 'skeletonization' of acid–soap layers[8].

Treatment of the multilayers with aqueous solutions containing polymeric anions, such as soluble silicates, alginate or tannic acid, renders them hydrophilic (in some cases with interference colour changes indicating increments of thickness); that is the analogue of the 'conditioning' of soap films with solutions of thorium and aluminum complex cations[9].

In addition to the chemical reactions already considered, it would appear that several other well-known reactions of amines offer potential for interesting modification of these L–B layers. Condensation with aldehydes has already been considered in the context of spread monolayers[10]. The formation of carbamate esters by reaction with chloroformates, or diazotization with nitrous acid, may also be possible. The amines, therefore, would seem to provide a highly useful addition to the materials suitable for L–B film fabrication.

I thank Dr R. S. McDonald for assistance with IR spectroscopy.

Photoreduction of methyl viologen in aqueous neutral solution without additives

Thomas W. Ebbesen, Gerrit Levey & Larry K. Patterson

Radiation Laboratory, University of Notre Dame, Notre Dame,
Indiana 46556, USA

Methyl viologen (paraquat; 1,1′-dimethyl-4,4′-dipyridinium dichloride; $MV^{2+}(Cl^-)_2$) has been of great interest not only for its herbicidal activity[1], but also for its use as an electron relay in photochemical systems designed for solar energy conversion[2–12]. In both cases principal attention has been directed towards the reduced species, that is the radical cation $MV^{+\cdot}Cl^-$ which can be generated through the photosensitized reduction of $MV^{2+}(Cl^-)_2$. Such reduction can be achieved *in vivo* by the photosynthetic system[1] or *in vitro* by Ru (II) tris-bipyridine derivatives[2–6], porphyrins[7–9], proflavine[10] and other aromatic compounds[12–14]. Direct photoreduction of $MV^{2+}(Cl^-)_2$ has been widely investigated in the presence of alcohols[15–18] and has also been noted in alkaline[19] and acid[20] solutions. Solid phase photoreduction of $MV^{2+}(Cl^-)_2$ on cellulose involving the oxidation of the substrate has recently been reported[21]. We describe here the direct photoreduction of methyl viologen in neutral aqueous solution to give the complex $MV^{+\cdot}Cl_3^-$. This is potentially important for the understanding of the herbicidal activity of methyl viologen. It also suggests an explanation for the photoreduction process of methyl viologen in alcohols and a possible extension of the role of methyl viologen in the photochemical conversion of solar energy.

Commercial $\mathrm{MV^{2+}(Cl^-)_2}$ (Aldrich) was recrystallized in pure ethanol and dried for 5 h at 70 °C. All solutions were prepared in 0.1 M phosphate buffer at $p\mathrm{H}=7$ and deoxygenated with $\mathrm{N_2}$. Using a Cary 219 spectrophotometer the absorption spectrum of $\mathrm{MV^{2+}(Cl^-)_2}$ was found not to obey Beer's law and may be shown to vary with added $\mathrm{Cl^-}$ concentration. This suggests formation of a complex between methyl viologen and the chloride ions. Indeed an association constant ($0.9\ \mathrm{M^{-1}}$) may be determined from the variation in the absorption spectrum. We believe this results from the complexation of the second $\mathrm{Cl^-}$ on the methyl viologen as has been suggested by others; conductance measurements have given an estimate of this association constant of the order of $10\ \mathrm{M^{-1}}$ (ref. 22). The behaviour of this complex is of great importance to the yield of photoproducts as will be discussed below.

On excitation of $\mathrm{MV^{2+}(Cl^-)_2}$ (0.1 M in 1 M NaCl) at 337 nm with a nitrogen laser (Molectron UV 400, pulse width 8–10 ns), transient spectra were observed (Fig. 1) which exhibit peaks at 395 and 605 nm characteristic of $\mathrm{MV^{\dot{+}}Cl^-}$ (ref. 23). The overall absorption by the initial transient (Fig. 1*a*) below 400 nm is, however, significantly higher than may be predicted from the known spectrum of $\mathrm{MV^{\dot{+}}Cl^-}$ (ref. 23) and the absorption measured at 605 nm. The presence of another transient species absorbing in the region below 400 nm is indicated. It may be seen from Fig. 2*a* that the transient formation occurs at a rate $>10^8\ \mathrm{s^{-1}}$, that is beyond the limits of our time resolution, and that decay occurs in a two step process (Fig. 2*b*, *c*). The initial transient spectrum (Fig. 1*a*) disappears with an overall experimental first-order rate constant, $k_\mathrm{D}=6\times10^4\ \mathrm{s^{-1}}$ (Fig. 2*b*), to a second transient spectrum (Fig. 1*b*). The latter spectrum is long lived, $>10^{-3}$ s (Fig. 2*c*).

While the long-lived transient may be assigned to $\mathrm{MV^{\dot{+}}Cl^-}$ alone (ref. 23), the initial spectrum, as indicated above, may not. However, it may be synthesized by summing the absorbances of equimola quantities of $\mathrm{MV^{\dot{+}}}$ (ref. 23) and $\mathrm{Cl_2^{\dot{-}}}$ (ref. 24). This is illustrated in Fig. 3 and is seen to give a good fit of the synthetic curve to the experimental points.

Such observation would suggest the oxidation of $\mathrm{Cl^-}$ by the excited state of $\mathrm{MV^{2+}}$ generated by photolysis:

$$\mathrm{MV^{2+}(Cl^-)_2} \xrightarrow{h\nu} \mathrm{MV^{\dot{+}}Cl_2^{\dot{-}}} \quad k_\mathrm{f}>10^8\ \mathrm{s^{-1}} \qquad (1)$$

This reaction is analogous to the photoreduction of the alkyl pyridinium ion in 1-alkyl pyridinium iodide[25] and of methyl viologen in the presence of carboxylate ions[22]. An equivalent reaction was previously[20] suggested to explain the simultaneous appearance of $\mathrm{Cl_2^{\dot{-}}}$ and $\mathrm{MV^{\dot{+}}}$ in acid solutions when irradiated in the UV with conventional flash photolysis. However, the transient spectrum given show that considerably more $\mathrm{Cl_2^{\dot{-}}}$ than $\mathrm{MV^{\dot{+}}}$ is formed. Furthermore, $\mathrm{Cl_2^{\dot{-}}}$ was formed in similar conditions in the absence of methyl viologen. Irradiation of chloride solutions in the far UV is known to produce $\mathrm{Cl_2^{\dot{-}}}$ as well as the hydrated electron, e^-_aq (ref. 26) and e^-_aq will reduce methyl viologen with a diffusion controlled rate constant ($8.4\times10^{10}\ \mathrm{M^{-1}\,s^{-1}}$) (ref. 23). The participation of such processes significantly complicates the mechanism for $\mathrm{Cl_2^{\dot{-}}}$ and $\mathrm{MV^{\dot{+}}}$ generation previously reported. In the present study, however, direct electron transfer occurs on excitation of the complex with light well into the visible part of the spectrum (see below) at biological pH.

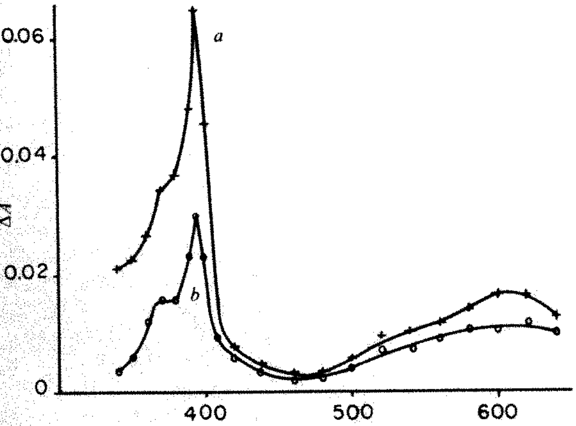

Fig. 1 Differential absorption (*A*) spectra of 0.1 M $\mathrm{MV^{2+}(Cl^-)_2}$ (1 M NaCl) after excitation at 337 nm with $\mathrm{N_2}$ laser (*a*, 1 μs; *b*, 35 μs after flash).

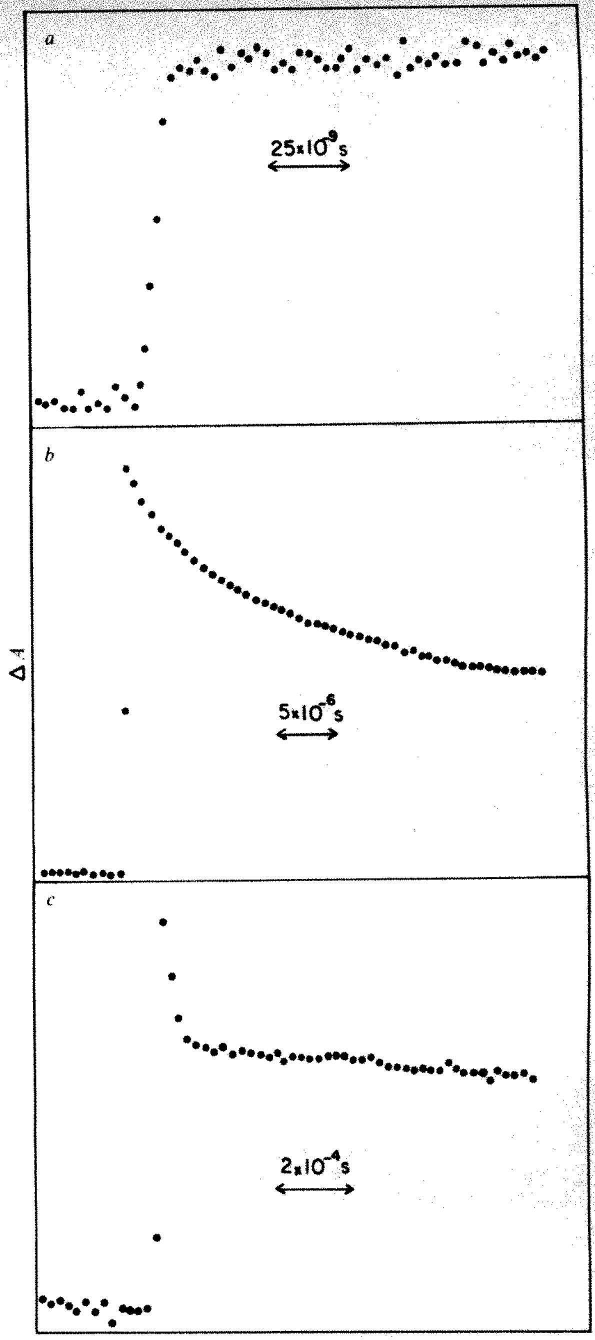

Fig. 2 Experimental kinetic traces of methyl viologen radical generation (*a*), its initial decay (*b*) and its long time disappearance (*c*) as observed at 395 nm after excitation at 337 nm of a 0.1 M $\mathrm{MV^{2+}(Cl^-)_2}$ (1 M NaCl) solution.

The quantum yield of reaction (1) strongly depends on the amount of ground state complex present. Using anthracene as reference[27,28] the quantum yield for reaction (1) with an excitation at 337 nm was estimated to be 0.2, in the experimental conditions described above.

The experimental first-order rate constant, k_D, is independent of wavelength, that is identical for $\mathrm{Cl_2^{\dot{-}}}$ at 340 nm and for $\mathrm{MV^{\dot{+}}}$

at 395 nm (absorption maxima for these species). k_D was also found to remain constant when the flash intensity was varied by a factor of 3. As a significant proportion of the radical cation $MV^{+\cdot}$ (spectrum Fig. 1*b*) remains after $Cl_2^{-\cdot}$ has disappeared, $MV^{+\cdot}Cl_2^{-\cdot}$ must decay by two different reactions. One of the reactions is the obvious back electron transfer:

$$MV^{+\cdot}Cl_2^{-\cdot} \rightarrow MV^{2+}(Cl^-)_2 \quad k_2\,(s^{-1}) \qquad (2)$$

The other reaction was found to involve $MV^{2+}(Cl^-)_2$ which was in excess in the solution:

$$MV^{+\cdot}Cl_2^{-\cdot} + MV^{2+}(Cl^-)_2 \rightarrow MV^{+\cdot}Cl^- + \ldots X \quad k_3\,(M^{-1}\,s^{-1}) \quad (3)$$

A simple kinetic analysis shows that the observed rate constant k_D is equal to the sum of k_2 and $k_3\,[MV^{2+}(Cl^-)_2]$. Values of k_2 and k_3 were determined to be $1.5(\pm1)\times10^4\,s^{-1}$ and $4.5(\pm1)\times10^5\,M^{-1}\,s^{-1}$ respectively. The rather large error limits arise from the limited concentration range over which the experiment can be performed. $MV^{+\cdot}Cl^-$ decays with a rate $<10^3\,s^{-1}$ (slow component in Fig. 2*c*) and no accumulation of the radical is observed under steady-state irradiation.

It is commonly believed that the toxicity of $MV^{2+}(Cl^-)_2$ in plants proceeds initially through its reduction by the photosynthetic system[1] and that the cation radical $MV^{+\cdot}(Cl^-)$ thus produced reacts with O_2 to give several toxic products[23,29–32]. While this is unquestionably the major toxic pathway, our results indicate, however, a potential parallel pathway: $MV^{2+}(Cl^-)_2$ absorbs light well into the solar spectrum (Fig. 4) and will thus directly generate not only $MV^{+\cdot}$ but also $Cl_2^{-\cdot}$. The presence of the radical $Cl_2^{-\cdot}$ adds another dimension to the toxicity of methyl viologen because $Cl_2^{-\cdot}$ is known to react at rates between 10^9 and $10^7\,M^{-1}\,s^{-1}$ with molecules such as: thymine, uracil, guanine, histidine, thyrosine, tryptophan, cysteine, ascorbic acid and other important biological molecules[33,34]. The redox potentials of $MV^{2+}/MV^{+\cdot}$ and $Cl_2^{-\cdot}/(Cl^-)_2$ are −0.44 V (ref. 35) and 2.3 V (ref. 36) respectively. Thus the energy necessary to drive reaction (1) can be estimated to be ~2.7 eV or a photon of 460 nm wavelength. However, the actual energy required might be less as the reaction proceeds with the complexed forms of methyl viologen. Using a dye laser with an excitation wavelength of 460 nm we were able to observe reaction (1), confirming, in accord with the theoretical estimate, that this phenomena is not limited to the near UV spectrum.

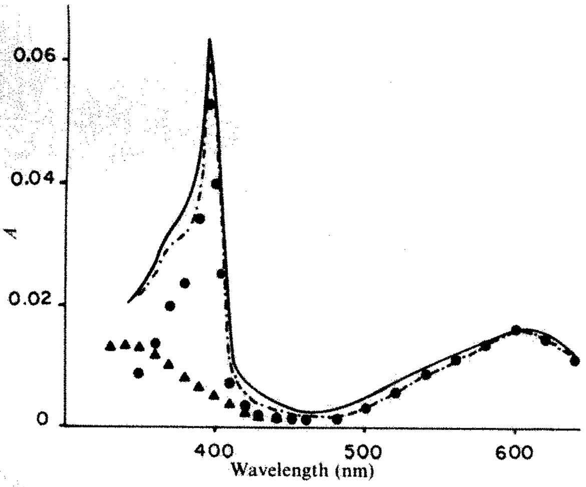

Fig. 3 Comparison between the experimental initial transient spectrum (———) of Fig. 1*a* and the theoretical spectrum (–·–·–) calculated assuming it to be the sum of the spectra of $MV^{+\cdot}$ ($\varepsilon_{605} = 11{,}000\,M^{-1}\,cm^{-1}$)(●) and of $Cl_2^{-\cdot}$ ($\varepsilon_{340} = 8{,}800\,M^{-1}\,cm^{-1}$) (▲) at an equimolar concentration of 1.5×10^{-6} M.

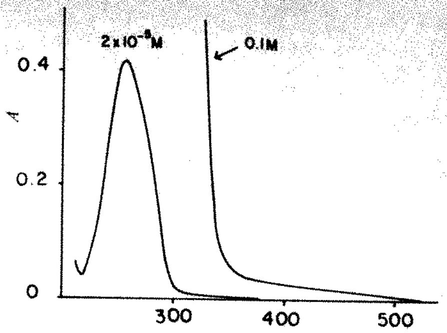

Fig. 4 Absorption spectra of $MV^{2+}(Cl^-)_2$ at 2×10^{-5} M and 0.1 M concentrations.

It is obvious that direct photoreduction of $MV^{2+}(Cl^-)_2$ in aqueous solution can compete with other indirect photosensitization pathways in solar energy conversion systems especially when near UV light is used. In fact, care must be taken to distinguish between the direct photoreduction and the photosensitized contribution in such situations. The methyl viologen radical is known to reduce H^+ in the presence of a catalyst, conversely $Cl_2^{-\cdot}$ can oxidize OH^- ($7.3\times10^6\,M^{-1}\,s^{-1}$) (ref. 34), H_2O_2 ($1.4\times10^5\,M^{-1}\,s^{-1}$) (ref. 34) and HO_2 ($4.5\times10^9\,M^{-1}\,s^{-1}$) (ref. 34). It is therefore not inconceivable that $MV^{+\cdot}Cl_2^{-\cdot}$ could have an important role in both reduction and oxidation of water.

The well known photoreduction of methyl viologen and its derivatives in alcohols has been shown to occur through two processes[37,38] (in certain cases quantum yields >1 have been reported[39]). The initial process may well resemble that observed here. $Cl^{\cdot}$ and $Cl_2^{-\cdot}$ are known to react with alcohols[26,40] and might generate the alcohol radical which in turn reduces another $MV^{2+}(Cl^-)_2$, thus accounting for the second process. While the presence of $Cl_2^{-\cdot}$ has not been previously suggested, a methyl viologen–alcohol–counter-anion complex has already been evoked to explain steady-state irradiation results of methyl viologen and aqueous alcoholic solutions[41]. Further study is in progress to elucidate this mechanism and other questions pertaining to the photoreduction of methyl viologen such as *p*H and temperature effects.

Air hydrate inclusions in fresh ice core

Hitoshi Shoji & Chester C. Langway Jr

Ice Core Laboratory, Department of Geological Sciences,
State University of New York at Buffalo, 4240 Ridge Lea Road,
Amherst, New York 14226, USA

One of the characteristic features of polar glacier ice is the abundance of air bubbles[1–3]. With increasing depth from the surface of the ice sheet, the size of the bubbles generally decreases in response to the change of overburden pressure. Below a certain depth, the bubbles start to shrink faster than expected and finally become invisible. Although not visible to the naked eye, unit mass of the bubble-free (clear) ice includes almost the same volume of air as unit mass of bubbly ice[4,5]. It is hypothesized that the air exists in the ice structure probably in the form of clathrate hydrates as suggested by Miller[6,7] but until now the location of the air has been unknown. Direct observations of air hydrate inclusions were carried out for the first time in fresh ice cores from Dye-3, Greenland. When the ice structure surrounding air hydrate was melted, an explosive transition occurred releasing a gas bubble into the melt cavity.

Optical microscope observations were carried out immediately after ice core recovery, as part of the mechanical property study project, during the 1980 and 1981 field seasons of the Greenland Ice Sheet Program (GISP) at Dye-3 (65°12′ N, 43°47′ W). The core was examined to locate the sites of the entrapped air in both bubbly and 'clear' looking ice samples. The work was conducted in a snow trench at −10 °C. Samples (2 × 2 × 1 cm) were cut from fresh ice cores using a band saw and then the surface was planed using a microtome. Silicone oil was applied between the ice sample and a glass plate and the upper surface was allowed to sublimate to diminish the light scattering. A tinker-dam made of shaved ice and supercooled water was applied around the sample to secure it to the glass plate. Thirteen samples were selected over the core profile as follows: 235, 504, 708 and 896 m depths from the 1980 ice core, and 939, 994, 1,280, 1,293, 1,537, 1,642, 1,711, 1,814 and 1,992 m depths from the 1981 ice core. Below 600 m, the ice became brittle with increasing depth and badly fractured between 800 and 1,200 m. The physical property of the core progressively improved and below ~1,400 m was of excellent quality. Total gas content measurements made on core samples at approximately the same depth levels showed a nearby constant gas volume concentration whether the samples were cut from bubbly or 'clear' ice. (S. Herron and C.C.L., in preparation).

To investigate the air sites, a device was constructed consisting of a variable transformer and a heated rod which permitted controlled melting. Microscopic observations were made at least 2 mm below the sample surface to avoid the strained layer near the surface.

Microscopic observations revealed that air bubbles disappeared completely at 1,642 m. However, transparent air hydrate inclusions appeared in the samples starting at a depth of 1,280 m. As is shown in Fig. 1, various shapes were observed for the air hydrate inclusions. They include platelet forms—triangular (*a*), hexagonal (*b*) and polygonal (*c*)—as well as forms classified as tetrahedron (*d*), polyhedron (*e*), graupel-like (*f*) and spheroid (*g*). These inclusions are easily distinguished from air bubbles by their low image contrast under the microscope. These transparent inclusions are not to be confused with Tyndall figures[8] (which consist of water vapour and liquid water), vapour figures[8] (only water vapour) or pressure cracks[1] (water vapour and air formed during the core relaxation process). The optical Becke test on the air hydrate inclusions revealed that the index of refraction of the inclusions is slightly higher than that of ice matrix surrounding them. This indicates that the transparent inclusions in Fig. 1 are not in a gas phase.

Figure 2 shows a typical response of an air hydrate inclusion when the temperature surrounding the inclusion is raised close to the melting point by the heated rod. An ice–water interface is located ~100 μm fron the inclusion and appears in the upper right-hand corner in Fig. 2*a–d*. A protuberance appears (a dark spot) at a position on the inclusion edge nearest to the ice–water interface as shown in Fig. 2*a*. The protuberance (a highly pressurized mixture of melt water and air from the inclusion) is further elongated as a column towards the ice–water interface (towards the high temperature side due to pressure melting) in Fig. 2*b* and finally the elongated column separates (Fig. 2*c*) and quickly migrates to the ice–water interface with a speed of 50 μm^{-1} s^{-1} merging in the melt water. This indicates that the

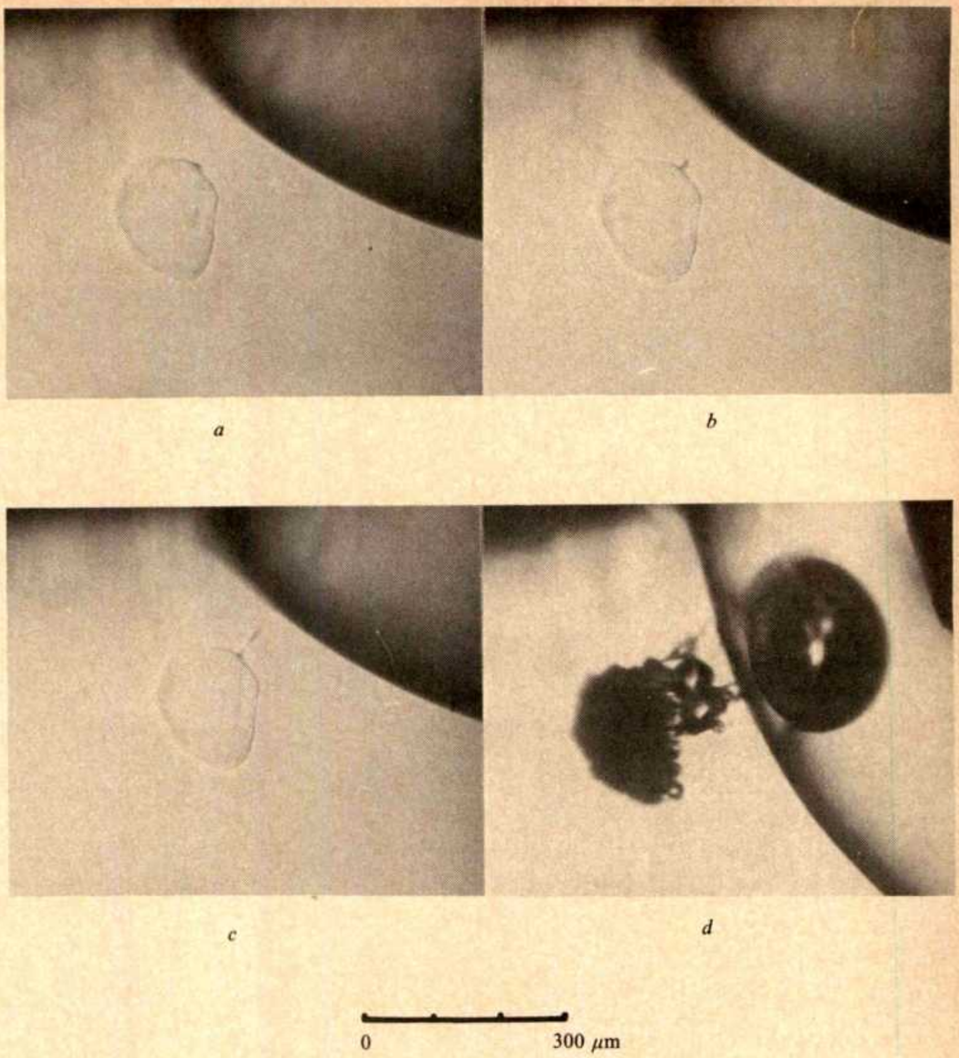

Fig. 2 The melting procedure of an air hydrate inclusion without air bubbles: *a*, embryo protuberance; *b*, elongated column; *c*, column separation (a jet); *d*, the transition of an air hydrate inclusion into air bubbles. Tip of heated rod is to be seen in the outermost upper right-hand corner of *d*; *d* also shows the explosive nature of the transformation of the air hydrate inclusion into a group of smaller air bubbles and the emergence of a huge amount of air into the melt water in the form of a large bubble.

inclusion is not in a gas or liquid phase under pressure. If it were, we would expect a migration or an expansion of the inclusion. In the examples shown in Fig. 2*b*, *c*, additional jets emerged every 20 s, but this frequency changed with each experiment. The rate of jet release is a function of distance between the inclusion and ice–water interface. The experimental procedure used created the end point shown in Fig. 2*d*. When the ice–water interface was moved forward by advancing the heated rod and made contact with the elongated column, an explosive transition of the inclusion into small bubbles occurred and a huge amount of air streamed out through the connecting channel to form a large bubble in the melt water as can be seen in Fig. 2*d*. When air bubbles exist in contact around the air hydrate inclusion before the heat treatment experiment as shown in Fig. 3, the response is different from that of air hydrate inclusions without air bubbles (Fig. 2*a*). A long channel (several hundred micrometres) formed perpendicular to the ice–water interface and air streamed out along this conduit into the melt water. A generation and expansion of multiple bubbles also occur inside the air hydrate inclusion. These observations under the heat treatment indicate that the transparent inclusion is a localized position for the air in clear bubble-free ice. Figure 4 shows a gradual transition of air hydrate inclusions into elongated air bubbles at −10 °C. Photographs shown in Fig. 4*a*, *b*, *c* were taken of the same transparent air hydrate inclusions at 12.5, 71 and 180 h. after core recovery from the bore hole. The two inclusions on the right side of Fig. 4 show air bubble appearance and growth. The size of the air bubble becomes greater than that of the transparent air hydrate inclusion in both cases (Fig. 4*c*), while the transparent inclusion remains the same size and shape. This clearly indicates that the transparent inclusion is in solid phase, otherwise appreciable change in the size or shape of the transparent inclusion would be affected by the hydrostatic pressure difference creating the growing air bubbles. On the other hand, the air hydrate inclusion on the left-hand side of Fig. 4 is still without air

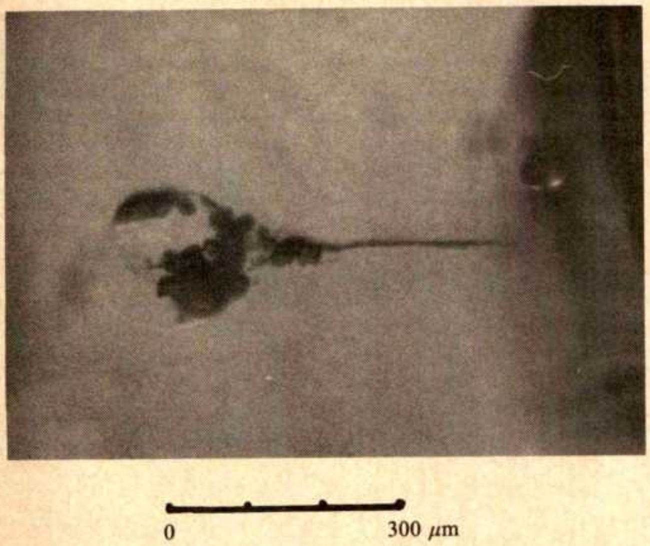

Fig. 3 A long channel formation from an air hydrate inclusion with existing air bubbles under heat treatment.

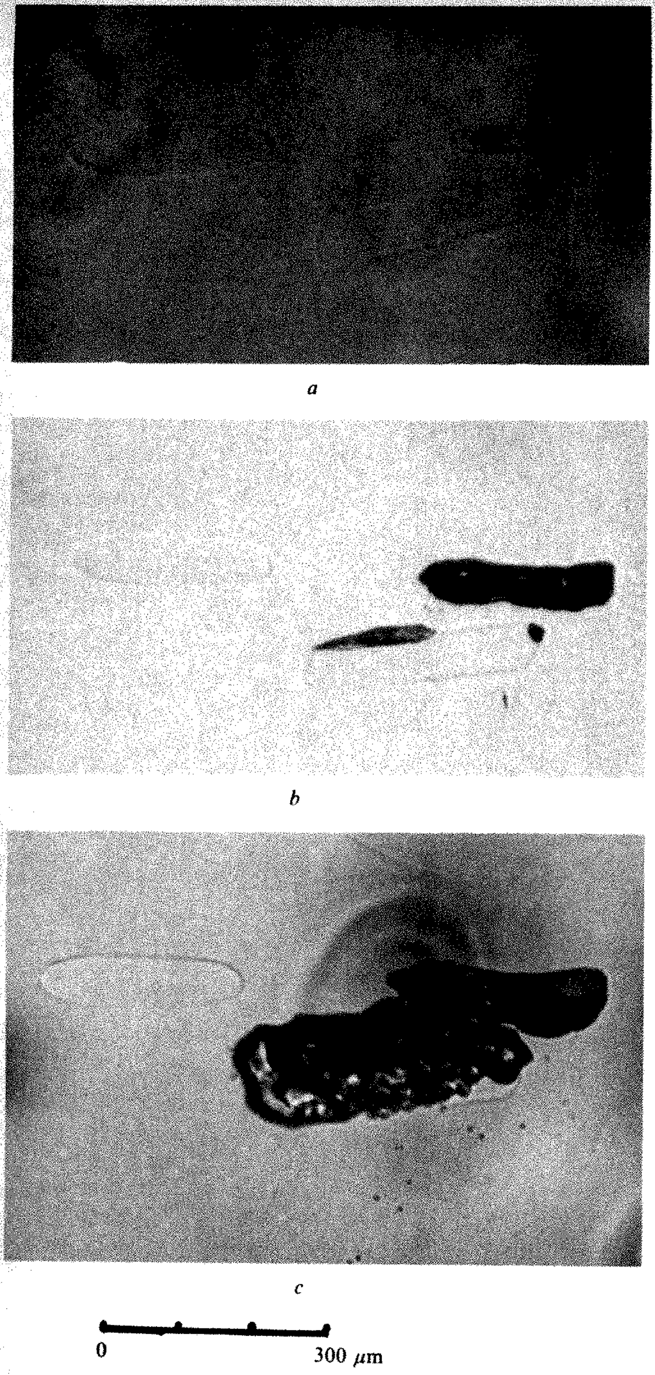

Fig. 4 Air bubble formation and growth process from air hydrate inclusions. *a*, *b* and *c* were taken at 12.5, 71 and 180 h respectively after core recovery.

bubbles even at the end of the 180-h experiment (Fig. 4*c*). This suggests that the nucleation for the phase transition of air hydrate inclusions fron solid to gas determines the rate of relaxation process of bubble-free ice.

The observations and results of this study indicate that the transparent inclusions are in solid phase and mainly composed of water and air molecules, that is, air hydrate inclusions. General information about the clathrate hydrate in ice cores have been given earlier by Miller[6,7] who has proposed calling it craigite. The amount of clathrate hydrate was calculated by Miller on the assumption that 10% of the volume of polar glacier ice consists of air bubbles. These bubbles originated at the surface as air voids and subsequently, through natural compaction processes, became entrapped in the ice. This is the situation at Dye-3. On the basis of the formula used by Miller, $(N_2,O_2)\cdot 6H_2O$, he calculated that 0.06% of the ice in volume would be clathrate hydrate of structure I. Our measurements show that 0.02% of the ice is occupied by air hydrate inclusions which are >10 μm in diameter and represents one-third the amount of the earlier calculation. This suggests that additional locations or smaller sized inclusions (<10 μm diameter) exist; for example, at interstitial positions[9] or grain boundaries. The depth for the first appearance of the air hydrate inclusions is somewhere between 994 and 1,280 m (a zone of highly fractured ice core) which nearly agrees but is slightly deeper than the 950 m value given by Miller for the clathrate hydrate at an *in situ* ice sheet temperature of about −20 °C. Supplemental observations on wedge-shaped thin section between crossed polaroids showed that the colour at the air hydrate inclusion is always shifted from that around the inclusion to that in the thinner part of the sample, which would be expected as the clathrate hydrate structure I is optically isotropic. These findings strongly support the possibility of the inclusion being a clathrate hydrate. A complete X-ray analysis for the crystallographic structure of the air hydrate is planned.

We thank Dr K. Itagaki and Dr B. Kamb for useful discussions. This work was supported by the NSF, Division of Polar Programs.

Major ion chemistry of some large Chinese rivers

Hu Ming-hui[*], R. F. Stallard[†] & J. M. Edmond

Department of Earth and Planetary Sciences E34-201, Massachusetts
Institute of Technology, Cambridge, Massachusetts 02139, USA

There is very little information available in the western literature on the chemical compositions of the major rivers of the People's Republic of China[1,2]. Since these include the largest in terms of sediment transport[3] (Huang He or Yellow), the third largest in terms of flow[4] (Chiang Jiang or Yangtze) and major streams draining the Tibetan plateau, this lack of data represents a significant gap in our knowledge of the chemical denudation rates of the continents as a whole and of south, central and eastern Asia in particular. To begin to rectify this situation, advantage has been taken of recent visits by US scientists to the People's Republic of China to collect suitable samples for analysis. It was found that the chemistry of such rivers is dominated by the weathering of carbonates and evaporites, with no pronounced effects of the degradation of aluminosilicates.

Given the *ad hoc* nature of the project samples were collected and processed in various ways. Those obtained by one of us (J.M.E.) were filtered and acidified soon after sampling. Those provided by our colleagues were either stored intact until

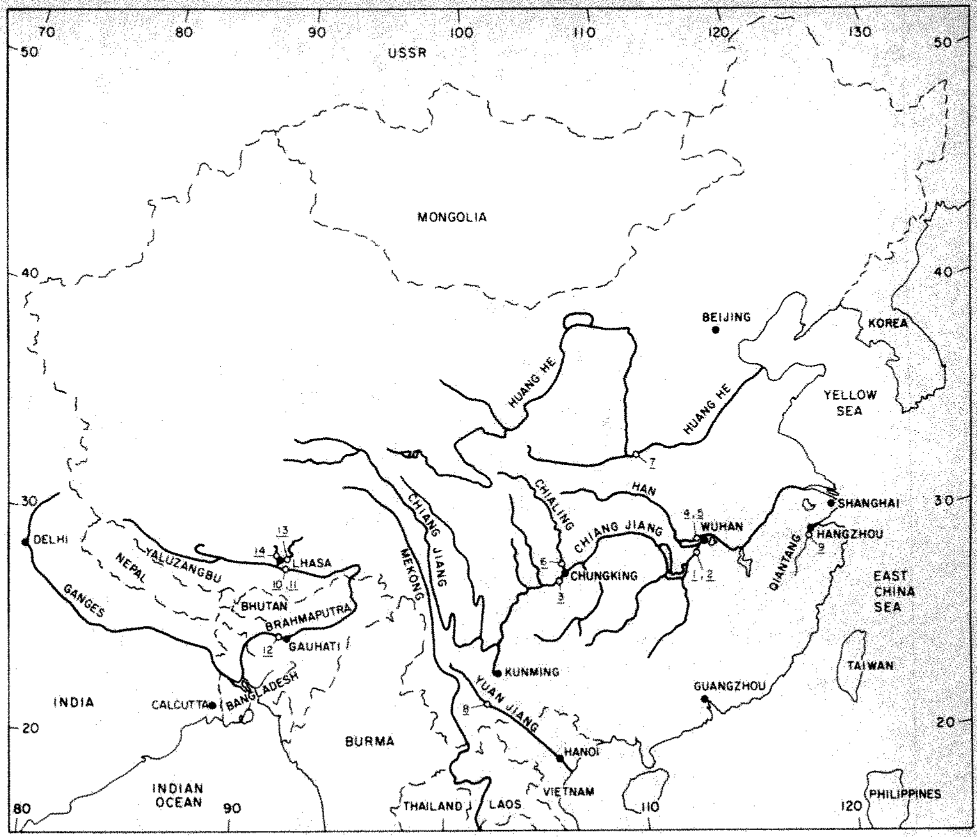

Fig. 1 Location map of the samples.

returned to the Massachusetts Institute of Technology laboratory, a period of several months, or were decanted after the bulk of the suspended material had settled out (within 24 h). The sampling locations are shown in Fig. 1 and these and the details of the processing are summarized in Table 1. The analytical procedures followed were as described previously[5]. The data are presented in Table 2.

Samples were obtained from the main channel of the Chiang Jiang at Chungking, above the Gorges, and at Wuhan in the central part of the flood plain (Table 1, Fig. 1). Two important southwards draining tributaries were also sampled at their confluence with the Chiang Jiang, the Chialing (at Chungking) and the Han (at Wuhan).

The tributaries are typical carbonate rivers with alkalinity accounting for over half the anion balance (including silica) (Fig. 2*a*). Calcium and magnesium are the major cations (Fig. H2*b*): (Ca+Mg)/(Na+K) is around 10 equiv. for the Han and 19 equiv. for the Chialing. In both rivers sulphate is substantially higher than chloride indicating a major contribution from the dissolution of gypsum and minor halite. The low silica and Na:Cl ratios confirm this and demonstrate the lesser relative importance of aluminosilicate weathering inputs in these basins. The main channel above Wuhan is rather similar in its properties, the chemistry being dominated by carbonate weathering (Fig. 2). At Chungking ($Cl+SO_4$) are more significant in the anion balance (Fig. 2*a*) with sulphate being particularly enhanced. This is a reflection of evaporite dissolution in the upper reaches of the river. There is a long established trade in salt in Szechwan and Yunan Provinces exploiting both salt springs and rock salt and supplying halite and gypsum to much of western China[6]. Aluminosilicate weathering is of minor importance consistent with the predominantly sedimentary geology of the drainage.

The Quiantang, sampled at Hangzhou, is an extreme example of carbonate weathering. Calcium and alkalinity account for over 85% of the cation and anion balances.

The Huang He is characterized by a very high content of dissolved solids ($0.46\ g\ l^{-1}$), over double that of the Chiang Jiang (Table 2). Chloride plus sulphate account for over 40% of the anions (Fig. 2*a*) and identify a major contribution from evaporites and soil salts[6,7]. It is estimated that the river loses ~50% of its flow to evaporation during transit around the Great Bend in a region of high aridity[8]. The Mg:Ca ratio of 0.72 and the high alkalinity suggest that carbonate is precipitated in this region also. The sodium excess over chloride (Na:Cl = 1.9) requires significant input from aluminosilicate

Table 1 Sample collection and processing

Sample no.	River	Date	Location	Processing
1	Chiang Jiang	October 1978	Mid-channel above Wuhan	Filtered within a few hours of collection
2	Chiang Jiang	June 1980	Mid-channel above Wuhan	Decanted after settling of suspended load
3	Chiang Jiang	June 1980	Jetty at Chungking	Decanted after settling suspended load
4	Han	October 1978	Mid-channel above confluence	Filtered

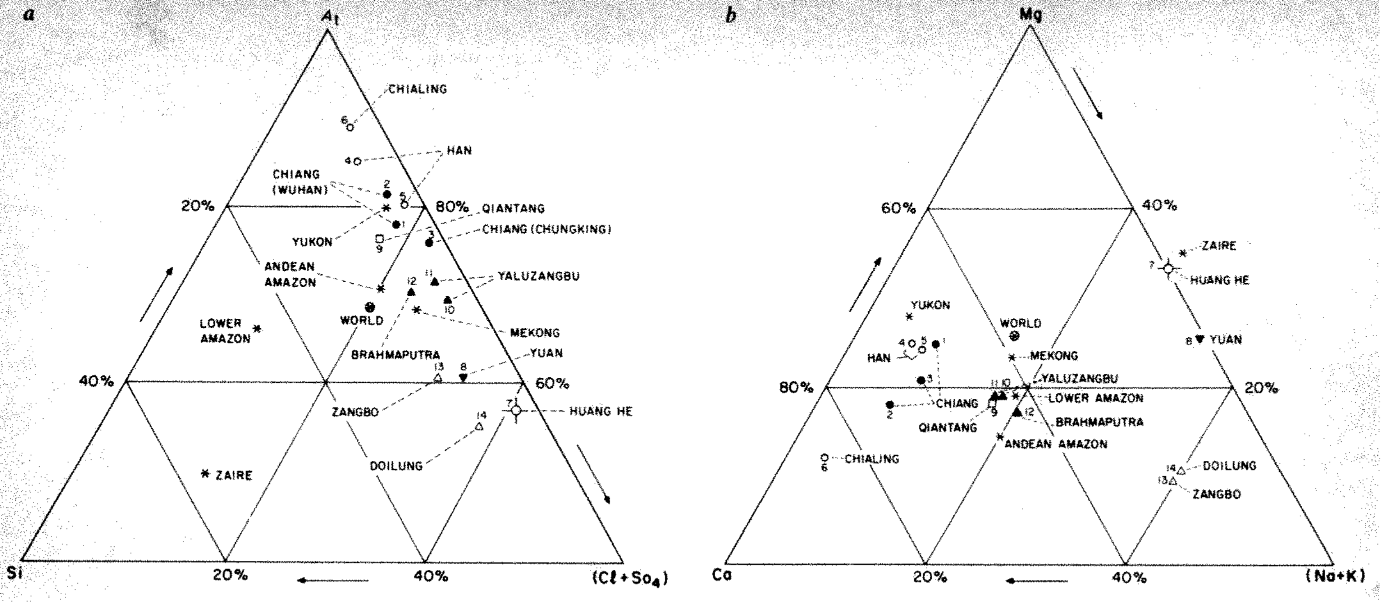

Fig. 2 *a*, Portion of the ternary diagram for the anions (including silica). The data are in equiv l^{-1}. Rivers draining siliceous terranes plot in the left-hand region (Si-A_t dominated). Those draining young orogenic belts rich in uplifted platform carbonates plot in the upper region (A_t dominated). The influence of evaporites is seen in the spread in the right-hand portion ($A_t - [Cl + SO_4]$ dominated). Rivers draining black shales plot in the lower central region owing to sulphuric acid weathering. *b*, Portion of the ternary diagram for the cations. While not as diagnostic as that for the anions parallel relationships are well developed.

weathering. The low silica value may be an artefact of removal by diatoms in the reservoirs upstream from the sampling site[8].

The Yuan Jiang has a chemistry rather similar to the Huang He although the concentration levels are much lower (Table 2, Fig. 2). Salt is mined extensively in the region of the drainage[9] and can account for the pronounced evaporite input. A similar effect is seen in the Mekong[10]. The sodium excess over chloride, the relatively high Mg:Ca ratio and the elevated silica require also a significant input from aluminosilicate weathering.

The chemistry of the Yaluzangbu–Brahmaputra in Tibet is offset from that of the Chiang Jiang in the direction of relatively higher evaporite inputs with sulphate substantially greater than chloride (Fig. 2). Published stratigraphical columns show evaporites in the Tertiary as well as reduced and perhaps pyritic sediments throughout[11]. The Tibetan samples are in marked contrast to that from the flood plain in the sub-Himalayan lowlands especially as regards the K:Na ratio. In rivers draining the Amazonian Andes, which like the Himalayas have an extremely moist 'front range' and dry interior[5,12], the chemistry is controlled by inputs from the well-watered tributaries[5]. While poorly described, the dominant lithologies of the moist slopes of the Himalayas appear to be reduced shales, gneisses, carbonates and perhaps volcanic rocks. Reduced shales are notably potassic[13] as are the gneisses and granites reported from the Himalayas[12]. Intense chemical weathering of these lithologies is consistent with the evolution of the river chemistry.

The two tributaries sampled drain portions of the Tibetan Plateau north of the main channel. They are carbonate–evaporite streams strongly enriched in sodium and chloride (Table 2).

The chemistry of the major rivers of China is dominated by the weathering of carbonates and evaporites (gypsum, halite) in varying proportions. The effects of the degradation of aluminosilicates are nowhere pronounced. In this, these rivers are typical of streams draining young orogenic belts. Thus the Chiang Jiang is very similar to the Yukon at the US–Canadian border (R.F.S and J.M.E. unpublished data) (Fig. 2) and the Yaluzangbu–Brahmaputra to the Andean Amazon in Peru[5]. In the latter case large-scale inputs of evaporite material from salt springs and exposed salt domes have been well documented[5].

The effects of aluminosilicate weathering have most influence on the anion diagram as they are uniquely characterized by high concentrations of dissolved silica. For illustrative purposes the Zaire (Congo) (R.F.S. and J.M.E. unpublished data) and lower Amazon[5] are plotted in Fig. 2. Both rivers receive a substantial component of their dissolved load from streams draining shield areas or, in the case of the Amazon, from basins whose surficial geology is dominated by shales or alluvial detritus. They are distinctively separated from the Chinese rivers on the anion diagram (Fig. 2*a*).

The Yaluzangbu–Brahmaputra, like the Mekong and the Andean Amazon, is close to the world average river water[1,2] in composition (Fig. 2). The Chiang Jiang and the Yukon are more calcareous, less siliceous and have lower relative abundances of alkalies, chloride and sulphate. The Huang He and Yuan Jiang are separate from the other rivers reflecting their

large evaporite inputs and, in the case of the Huang He, probable artefacts of carbonate and silica removal during evaporative loss or in reservoirs.

A rough estimate can be obtained of the transport of dissolved material by these streams by combining the compositional data reported here with the existing discharge measurements[4] (Table 3). Note that such calculations are uncertain by as much as 50% because of the variations in the discharge-composition relationship over the range of the discharge and because of the lack of information on the actual flow rates at the time of sampling. These effects can be seen by comparison of values of the chemical transport from rivers resampled on different dates (Tables 1.3). Estimates for the Amazon[5], Zaire (R.E.S. and J.M.E., unpublished data) and Mekong[10] are shown for comparison as are the global estimates[1,2].

Although its discharge is less than one-fifth that of the Amazon, the Chiang Jiang carries substantially more calcium, magnesium, sulphate and alkalinity to the ocean. It supplies lesser but still relatively large amounts of sodium and chloride. Its transport of potassium and silica is similar to that of Zaire; the latter is a relatively minor supplier of the other major ions reflecting the low weathering yields from siliceous terranes.

The Huang He, although its discharge is small (1% of that of the Amazon) is a significant source of sodium, chloride and sulphate. It contributes only a small amount of potassium.

The Yaluzanbgu–Brahmaputra, with a discharge of ~60% of that of the Chiang Jiang, supplies considerably more potassium and appreciable amounts of sodium, chloride and sulphate. It is much more potassic than the Mekong, with similar discharge, but comparable for the other elements.

In the global context, the Chiang Jiang accounts for over 5% of the flux of magnesium, calcium, chloride, sulphate and alkalinity to the oceans. Neither the Yaluzangbu–Brahmaputra nor the Huang He make contributions of similar magnitudes. The total salt discharge of the Chiang Jiang is $\sim 220 \times 10^6$ tonnes yr^{-1} or 226 including silica. This places it equal to the Amazon at 223×10^6 tonnes yr^{-1}.

Estimates of the average chemical denudation rates for the basins can also be derived from the data (Table 3). As compared with the world average[1,2] these are high for rivers with well-watered, topographically elevated drainages composed of young orogenic belts—Chiang Jiang, Yaluzangbu–Brahmaputra, Mekong. They are close to the average for streams draining arid mountainous regions—Huang He—or extensive lowland areas—Amazon. They are very low for rivers such as the Zaire which drain predominantly shield terranes.

The inferences as to carbonate–evaporite versus aluminosilicate weathering are substantiated by the variations in the ratio of the areal yields of alkalinity and silica. These range from 20 for the Chiang Jiang (40 for the Huang He, probably an artefact), 7 for the Yaluzangbu–Brahmaputra and Mekong to 1.4 for the Zaire. The world average is 4.8 again emphasizing the extreme chemistry for the Chiang Jiang.

With the exception of the Huang He the major rivers of the People's Republic of China are free from large-scale hydrological development. Outside of their lowermost reaches agriculture is the only anthropogenic modification that can be expected to have a significant influence on the water chemistry. It is to be hoped that systematic geochemical studies will be initiated before and pursued in parallel with the planned industrial development of the basins.

We thank the US Committee for Scholarly Communications with the People's Republic of China and especially Mr Halsey Beemer for their generosity and support. We also thank the parallel organizations in the People's Republic of China. We are grateful to H. and V. Craig, B. Lyons, P. Molnar and C. Nordin for contributing samples. R.F.S. acknowledges the receipt of an NSF graduate fellowship.

Dynamic uplift of the Himalaya

Chi-yuen Wang & Yao-lin Shi

Department of Geology and Geophysics, University of California, Berkeley, California 94720, USA

Wen-hu Zhou

Institute of Geophysics, Academia Sinica, China

It has become widely accepted that the Himalaya is the product of collision between the Indian landmass and the Eurasian continent. Holmes[1] conjectured that the Indian Shield was carried northwards by sub-lithospheric mantle flow to cause a double thickening of crust beneath the Himalayas and the Tibetan Plateau. Wager[2] hypothesized that the extra height of the great peaks of the Himalaya over Tibet was due to isostatic readjustment following the removal of load by intense erosion. Molnar *et al.*[3], relate the uplift to the shear stress on the boundary faults beneath the Himalayas. Relevant data have recently become available from the northern flank of the Himalaya and the Tibet Plateau, of which especially important are: (1) a gravity profile across central Tibet; (2) seismic crustal structures of the region from explosion seismology; (3) seismicity; (4) geothermal activities; (5) geodetic, palaeogeographical, and radiometric data bearing on the uplift rate of the region; and (6) field observation of the surface fault patterns. The combined data-set has imposed strong constraints on theories of the dynamic processes in this region. We summarize here the relevant observations and discuss the results and implications of our model analysis; details of the modelling procedure are given elsewhere[4].

Gravity surveys along a 1,200 km highway across central and eastern Tibet, from Yadong (27.88° N, 88.56° E) to Golmud

0028-0836/82/310553—04$01.00

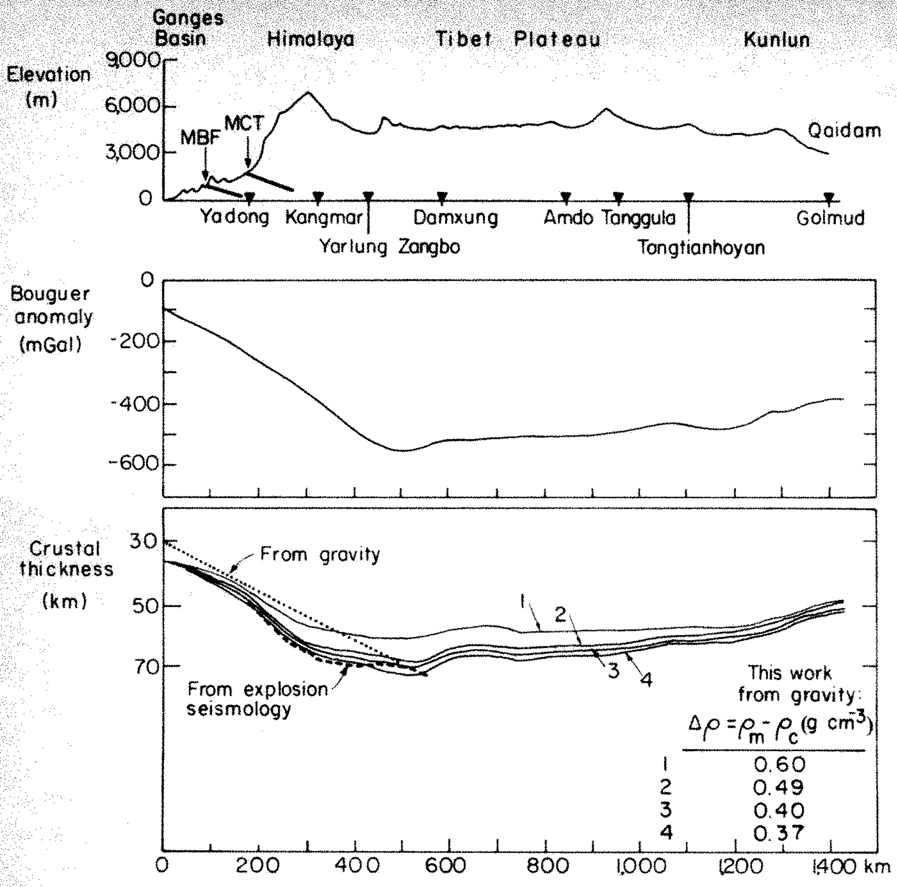

Fig. 1 Topography and Bouguer gravity anomaly along the cross-section from Yadong (27.88° N, 88.56° E) to Golmud (36.22° N, 94.55° E). The corresponding boundaries for an Airy crust are also plotted, based on a normal crustal thickness of 30 km and several values for the density contrast between the crust and the upper mantle. The dotted line shows the boundary given by Kono[35]. The dashed curve shows the Moho boundary obtained from the explosion seismology[5].

(36.22° N, 94.55° E), were carried out in 1975–77. Figure 1 shows the topography and the Bouguer gravity anomaly along this route. North of the Zangbo River, Tibet is characterized by a large negative Bouguer anomaly of about −500 mGal. Southward from the Zangbo River, Bouguer anomaly increases from about −500 to −300 mGal over the High Himalaya and to about −50 mGal over the Ganges Basin. The Airy crust constructed from this gravity profile is also shown, which is about 70 km thick beneath the Tibet Plateau, but thins southward to about 50 km beneath the High Himalaya. This model is supported by its general agreement with the latest information on the seismic velocity structures of this region.

Seismic profiling in central Tibet along the 90° E meridian[5] has provided the most detailed information for the crustal structures. The crusts on the two sides of the Zangbo River are significantly different. North of the river the crust is 70–73 km in thickness; south of the river the crust thins from 65 to 45 km near Yadung (27.5° N). Deep seismic sounding in the Kashmir Himalaya shows northward dipping of the Moho at an average angle of 15°–20° (ref. 6). Thus, the Moho boundary has the same general features as the lower boundary of the Airy crust.

Most of the seismic activity is confined to the southern slope of the Himalaya. Along most of the Himalaya the seismic activity appears to be associated with the Main Boundary Fault (MBF)[3]. On the other hand, Chandra[7] located earthquakes in a broad zone of 200-km width along the Main Central Thrust (MCT), and considered both the MBF and MCT to be active. Most earthquakes are generated by thrust faulting, with one plane dipping gently beneath the Himalaya[3]. This is consistent with the theory that the Indian subcontinent underthrusts at shallow angles, and implies that the processes that formed the Himalaya are still at work.

Within the Tibet Plateau, seismic activities are less vigorous, and the fault plane solutions generally show strike-slip faulting, with the P-axis oriented approximately north–south[8], or normal faulting, with the T-axis oriented approximately east–west[9–11]. Studies of Landsat imageries[10] and recent field observations[12,13] also revealed abundant evidences for active strike-slip and normal faulting inside Tibet.

Geothermal activities in Tibet (Fig. 2) are extremely energetic with numerous boiling springs, geysers, and hot springs scattered across the highland. Cenozoic volcanism is extensive over much of Tibet. Youthful geology also points towards a high regional heat flow.

Also important is the uplift rate of the Himalaya. Geodetic surveys[14] in northern India during the past 75 yr revealed that the block north of the MBF is uplifting with respect to the southern block at an average rate of 0.8 mm yr^{-1}. Fossil fauna, including *Hipparion*, were recently found in the horizontally bedded lake deposits of Jilong Basin (20°30′ N, 85°10′ E), now at an elevation of about 5,000 m (refs 15, 16). Widely distributed peneplains in the High Himalaya at similar elevations are thought to be the remains of an originally continuous peneplains formed in the Pliocene at about 1,000 m above sea level[17]. Evidences from abundant pollen, plant fossils, and traces of ancient snowlines have made possible the separation of the influences of the climatic factor from the tectonic one[18–20]. These palaeogeographical investigations have yielded a consistent estimate that an average uplift rate of ~1 mm yr^{-1} has occurred in the High Himalaya since the late Pliocene. A third type of estimate of the Himalayan uplift rate came from modelling fission-track dates of minerals from this region; a consistent estimate of uplift rate from 0.7 to 1.5 mm yr^{-1} also emerges from these studies[21,22]. Clearly, there is much uncertainty in each of these estimates, and more extensive work is needed to gain a more precise knowledge of the Himalayan uplift rate; but when all the evidence is taken together, the close agreement in the different estimates is not likely to be coincidental, and the estimate of an average rate of uplift of 1 mm yr^{-1} seems to be reasonable.

Based on these observations, we have attempted to model the present tectonic process in this region by using a two-dimensional, finite element technique[4]. Deformation was approximated by plane-strain in a vertical plane perpendicular to the major structural lines, with the north–south width of the model extending northward from the Ganges Basin, through the Himalaya and the Tibet Plateau, to the Kunlun Mountains. Such an approach is common for problems where the vertical motion is of main concern[23]. As mentioned above, however, most earthquakes inside Tibet are either due to strike-slip faulting, with the P-axis nearly in the north–south direction[8], or due to normal faulting, with the T-axis in the east–west direction[9–11]. Thus, the problem of modelling the tectonics in the Himalayan–Tibet region is intrinsically three-dimensional. Nevertheless, a two-dimensional approximation of the problem may be worthwhile, not only because it is far less expensive but because it may provide insight to the complex problem at hand.

The detailed modelling procedure is given elsewhere[4]. We assumed that at shallow depth the crust is permeated with fractures so that deformation is controlled by frictional sliding. At deeper levels ($\geq \sim 25$ km) ductile flow becomes more important; the controlling mode of deformation is assumed to be the one that requires less shear stress to activate. For frictional sliding, the shear stress (τ) and the normal stress (σ_n) across the sliding surface are related by $\tau = \mu\sigma_n$ where μ is the frictional coefficient and is ~ 0.6–0.8 for rock-on-rock sliding[24,25] and may decrease to 0.2 for faults filled with saturated clayey gouge[26]; the latter value is used for friction on the boundary faults beneath the Himalaya. For steady-state flow of rocks at high temperature, the general relation between strain rate ($\dot{\varepsilon}$) and the deviatoric stress ($\delta\sigma$) may be expressed at $\dot{\varepsilon} = A(\delta\sigma)^n \exp(-Q/RT)$, where T is the absolute temperature, R is the gas constant, and A and n are material constants. From the steady state flow laws for several crustal rocks recently reported by Shelton and Tullis[27] we chose for the lower crust the following parameters: $Q = 60$ kcal mol^{-1} (251 kJ mol^{-1}), $n = 3$, and $A = 1.33 \times 10^3$ kbar^{-3} s^{-1}. For the upper mantle we assume that the steady state flow is controlled by the mechanical properties of olivine. The experimental results are summarized by Tullis[28]. For our numerical work, we chose the following parameters: $Q = 100$ kcal mol^{-1}, $n = 3$, and $A = 3 \times 10^8$ kbar^{-3} s^{-1}.

Because the mechanical properties of rocks depend strongly on temperature, its value beneath the Himalaya and its vicinity is a most important factor. Unfortunately, relevant data for the construction of geotherms in this region are tenuous. Beneath the Ganges Basin, we adopted the thermal model of Bird[29] for the Indian platform. Chen and Molnar[30] recently interpreted the upper mantle seismic velocities beneath Tibet, using laboratory data for olivine at high temperature and pressure, they concluded that the upper mantle temperature beneath Tibet is about 250 °C higher than that beneath the Indian Shield at the same depth. This conclusion is consistent with the high geothermal activities in this area (Fig. 2), and confirms a geotherm we constructed from an assumed high conductive heat flow (2 HFU) and some broad geophysical constraints[4].

With these assumptions of rheology and geotherms, the mechanical property of our model is defined. The depth where ductile flow becomes dominant depends on the local strain rate and the geotherm. In general terms, the upper 25 km or so is stiff, below which ductile deformation becomes more important and the 'strength' of the lithosphere decreases rapidly with depth.

Assuming that the observed gravity anomalies and uplift in this region is the product of a tectonic process still in operation, we looked for a set of boundary conditions which led to predictions compatible with observations. The successful boundary conditions were then used to constrain the mechanism which may now be operating for the Himalayan uplift.

From the many models we tested[4], the best one was acquired by imposing the following boundary conditions (Fig. 3): the south boundary moves northwards with a velocity of 50 mm yr^{-1}. On the bottom boundary, vertical movement is $\sim$2 mm yr^{-1} under the thrust zone and 1 mm yr^{-1} under the Tibet Plateau, horizontal displacement is not constrained, except under Tibet, where a basal shear of a few bars is applied in the direction opposing the plate motion. The northern boundary is fixed in position at its lower end, but the upper 25 km is constrained to move northward at a rate of 10 mm yr^{-1}. This causes the lower crust and the upper mantle to experience a horizontal shear.

Results of calculation for this model (Fig. 3) show that the Ganges Basin sinks and the Himalaya rises, with a calculated uplift rate for the Himalaya of $\sim$0.6 mm yr^{-1}, relative to the Ganges Basin. Considering the substantial uncertainty usually present in such data, and considering the crudity of our model, we think the agreement between the calculated and the observed values are satisfactory. The Tibet Plateau also uplifts; at the same time it remains in isostatic balance. But the Himalaya and the Ganges Basin do not; the Himalaya develops a positive isostatic anomaly, and the Ganges Basin a negative anomaly. The thickening of the crust in Tibet is accompanied by shortening of the entire region, with $\sim$15% in the Ganges Basin, $\sim$30% in the Himalaya, and $\sim$55% in Tibet. When the stability of this model was examined with respect to changes in material properties and boundary conditions, it was found that it was stable to minor changes of material properties and boundary conditions.

An interesting result is the differential uplift rates between the Tibet Plateau and the Himalaya—the annual rate of uplift of the Himalaya is $\sim$0.2 mm yr^{-1} greater than that of Tibet. This difference in uplift rates implies that the Himalaya was lower than Tibet some 2 Myr ago. Spectacular evidence for this speculation is provided by the many antecedent rivers flowing southward across the main ridges of the Himalaya[1,2]. Following Wager[2], we suggest that the rivers established their courses on a slope which formed the descent from a northern highland (which was later elevated to become the Tibet Plateau) to the Ganges plain, and since then the Himalaya has risen faster than

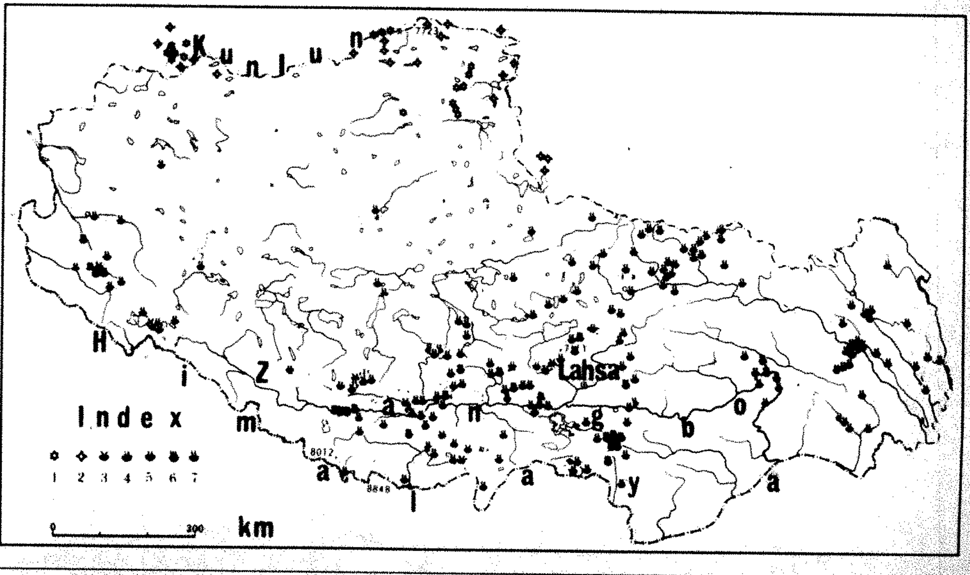

Fig. 2 Geothermal activities in Tibet[36]. 1, Quaternary volcanic cones; 2, eroded volcanic cones; 3, steam blasts; 4, intermittent hot springs; 5, geysers and fumaroles; 6, boiling springs; 7, hot springs.

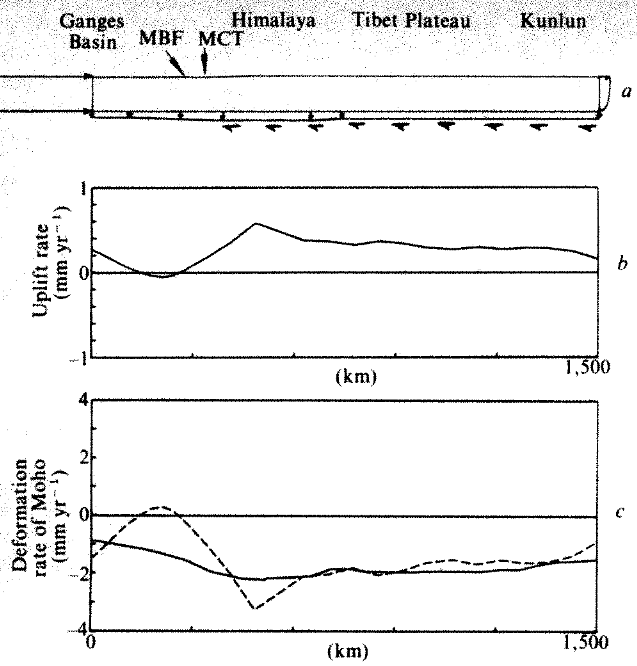

Fig. 3 *a*, Boundary conditions used in obtaining our 'best-fitting' model. The displacement boundary condition is indicated by arrows. The traction at the bottom boundary of the model is indicated by the 'half' arrows. *b*, Calculated annual rate of deformation at the surface. *c*, Calculated annual rate of deformation at the Moho boundary. The solid curve gives the deformation rate for the model; the dashed curve shows the hypothetical position of the boundary if local isostasy is achieved. Thus, if the dashed boundary lies above the solid boundary, the region is overcompensated and will show a negative isostatic gravity anomaly; on the other hand, if the dashed boundary lies below the solid boundary, the local region is undercompensated and will show a positive isostatic gravity anomaly.

Tibet to cross the rivers' courses. More evidence is provided by the studies of the palaeoclimate on the northern flank of the Himalaya[19,20]. These studies show that up until the middle Pleistocene the Himalaya did not significantly block the moisture from the south. Since the late Pleistocene, however, the mountain range has become a barrier effective enough to cause a dramatic change to a dry and cold continental climate on the northern flank of the mountain range and inside Tibet.

The calculated maximum principal stress in the model is compression in the horizontal plane and along the north–south direction. Under the Himalaya, the stresses along the thrust faults are also compressive, in conformity to the seismic focal mechanism. The magnitude of the predicted stresses depends critically on the assumed rheology and, in the lower crust and the upper mantle, on the assumed geothermal profiles. Our predicted stresses, however, are compatible with the current thinking on the formation of the Himalaya. On the average, our calculated maximum shear stress increases from about 1 kbar at a depth of 5 km to a maximum of 3 kbar, and then decreases to about 1 kbar at 45 km, 100 bar at 60 km, and about 1 bar at 100 km. The maximum stress difference beneath Tibet required to support the static loading due to the anomalous mass associated with the topography was estimated to be 0.5–1.5 kbar. Our calculation shows, however, that the tectonic stresses in this region may be significantly greater than the static stresses induced by surface loading. This tectonic stress has caused India to underthrust the Himalaya and is resisted by buoyant forces and friction. The push from the south and the resistance from below may have forced the Himalaya to uplift quickly to reach its great heights within recent geological time.

The highest values of the maximum shear stress, as predicted by our models, occur near the southern boundary and the lowest values under Tibet. The differences between these values remain within a factor of 2–5. This lateral variation of shear stress may be partially responsible for the southward migration of faulting in the Himalaya. Molnar *et al.*[3] relate this southward migration of faulting to increasing friction on the active fault beneath the rising Himalaya. The mechanism we suggested above is complementary to that suggested by Molnar *et al.*

Because of the two-dimensional nature of our model, we cannot predict the observed patterns of normal faulting or strike-slip faulting in Tibet. Surface deformation patterns, however, are not clearly related to the state of stress at depth. To demonstrate this point, we have carried out a preliminary, three-dimensional finite element calculation of the deformation of a model consisting of a upper, stiff, layer overlying a lower ductile substratum under uniform north–south compression. Our results show that east–west tensile stress may be induced in the upper layer to cause extensional features. A similar conclusion was reached qualitatively by Molnar and Tapponnier[31,32]. Other mechanisms, such as doming and stress concentration near the tips of pre-existing faults may also produce east–west extension under north–south compression. Thus, the observed tensional features on the surface in Tibet do not necessarily contradict our suggestion that the entire region is under a north–south compression. Studies of the focal mechanism of intermediate depth earthquakes beneath Tibet would provide crucial evidence for further modelling. Hong *et al.*[33] studied the focal mechanisms of seven earthquakes of intermediate depths in this region and showed a consistent picture of slightly inclined *P*-axes perpendicular to the main structural lines. Chen *et al.*[34] did a more detailed study of one intermediate depth earthquake in Tibet; their results, however, shows the *P*-axis to be vertical. Clearly, more work needs to be done towards a better understanding of the tectonics of this region.

We thank Peter Bird, and John Verhoogen for helpful comments. C-y. W. thanks the University of California for financial support, the Academia Sinica for making possible his trip to the studied area, and Zhang Zhi-fei for permission to include his geothermal data.

Analysis of interspecific interactions in a coastal plant community—a perturbation approach

J. A. Silander & J. Antonovics

Ecology Section, Biological Sciences Group,

and Department of Botany, Duke University, Durham,
North Carolina 27706, USA

Most studies of plant communities attempt to correlate species distributions with environmental variables[1-5]. Such studies provide some insight into the contribution of density-independent variables to plant community structure[1-6] but contribute little to our understanding of niche relationships and levels of competitive interactions among coexisting species. In contrast, experimental perturbation studies where species are added or removed, have the advantage of testing specific biotic interactions among community components in natural conditions. Such approaches, for example, have proved valuable in elucidating the role of competition and predation in structuring sessile marine invertebrate communities[7-9]. Despite an empirical approach championed by Clemments[10], few terrestrial plant ecologists have conducted analogous perturbation–response studies[11-14]. We have performed perturbation experiments on a set of closely adjacent coastal plant communities. Our observations indicate that species interactions are important in structuring these plant communities, and that these interactions may be specific or diffuse, reciprocal or non-reciprocal and may vary in different environments. We suggest a general approach to quantifying species interactions, derived from perturbation experiments, as a framework for generalizations and comparisons of biotic interactions in natural communities.

A series of adjacent coastal plant communities was examined along a gradient across Core Banks, a barrier island on the coast of North Carolina. The vegetation was surveyed by measuring optical point cover in 448 0.25 m^2 contiguous quadrats located along two main transects across the island and several smaller transects chosen to include the total range of communities encountered in the area. A single environmental scalar was developed from two measured environmental variables (distance from beach berm crest and depth to water table), using direct gradient ordination[1,15]. From relative cover values, we obtained running average curves for each species along the scalar (Fig. 1). Detailed analyses of these ordinations will be presented elsewhere. Several workers have attempted to make interpretations regarding niche relationships among coincident species from such descriptive data[16-20], but these purely observational data beg the question of whether species both coexist and compete, or coexist because they do not compete.

Experimental perturbations were carried out at five sites approximately 50 m apart along one of the main transects in the primary dune, rear dune, swale-grassland, high salt marsh, and low salt marsh. Dominant and subdominant species were removed singly or in groups within 1 m^2 plots by weeding, combined with selective herbicides. At each site there were two or four selective removal treatments (see Fig. 2 and Table 1), complete vegetation removal, plus a control. Grasses and sedges were spot- or broadcast-treated with Dalapon (2,2-dichloropropionic acid) and dicotyledons with (2,4-dichlorophenoxyacetic acid (2,4-D). Treatments were repeated as necessary to ensure that vegetative regrowth did not occur during the first 3 months of the study (June–August). At each site, treatments were assigned randomly to cells in each of three replicate blocks. Four samples were taken per cell for a total of 12 replicates per treatment per site. Species responses were analysed by optical point cover (0–81 counts per replicate) and, for grasses, by change in the number of tillers per year. The results of both methods were very similar[21], and only values based on optical point cover are presented (Fig. 2 and Table 1).

Removal effects were tested by analysis of variance (after square root transformation) in which treatments were contrasted with controls in paired comparisons. Using block × treatment mean square as the error mean square, significant removal treatment effects were found in 8 of 48 comparisons [$\alpha = 0.05\ (1,2)$] (Fig. 2 and Table 1) whereas <3 would have been expected by chance at this level. We use this result to show that significant species interactions can potentially be resolved by such perturbation–removal experiments.

It is possible that the within-block replication differs from that between blocks; in this case it would be invalid to combine error variation. A subjective assessment of the experimental area indicated that the two levels of variation were similar for most of the cells. In addition, the mean square errors associated with the within-cell replicates were approximately equivalent to the block × treatment mean square errors for 40 of 48 comparisons. We therefore pooled the error variation for each comparison[22] and have given the appropriate standard errors in Table 1.

We now introduce a general approach to analysing these biotic interactions: the response of species j to the removal of species i can be quantified in terms of a removal response coefficient defined as $C_{ij} = N_{ij}/N_i$, where, N_{ij} is the change in importance of species j following the removal of a coincident species i, and N_i is the importance value of species i coexisting with species j before the imposed perturbation. Here importance values are based on per cent cover, but abundance, biomass, reproductive output and so on, might be used. N_i is equivalent to the relative area of the central, darker circle in

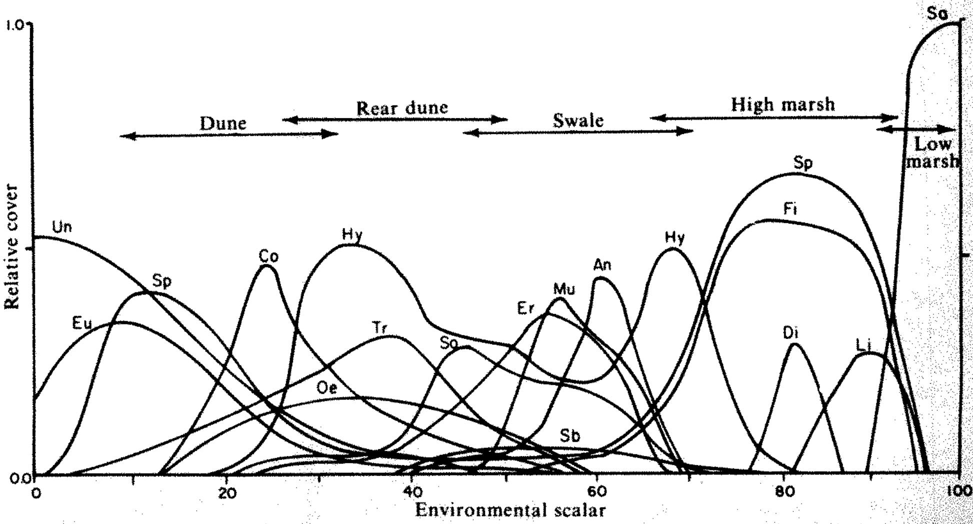

Fig. 1 Direct gradient ordination for 16 herbaceous species occurring along the Core Banks, North Carolina transects. The environmental scalar is based on a weighted distance from the beach and the inverse of depth to the water table. Species curves were plotted from running averages. Abbreviations for species are as follows: Un, *Uniola paniculata*; Eu, *Euphorbia polygonifolia*; Sp, *Spartina patens*; Co, *Conyza canadensis*; Oe, *Oenothera humifusa*; Hy, *Hydrocotyle bonariensis*; Tr, *Triplasis purpurea*; So, *Solidago sempervirens*; Er, *Eragrostis pilosa*; Mu, *Muhlenbergia capillaris*; Sb, *Sabatia stellaris*; An, *Andropogon scoparius*; Fi, *Fimbristylis spadiceae*; Di, *Distichlis spicata*; Li, *Limonium carolinianum*; Sa, *Spartina alterniflora*.

0028–0836/82/310557—04$01.00

each diagram of Fig. 2; N_{ij} is equivalent to the relative area of the jth inner, tangential circle associated with each N_i.

In most cases, coexisting species increased in importance after the removals. However, in one case, *Eragrostis* showed a large decrease in importance (negative C_{ij} value) following the removal of *Spartina patens* from the swale. This effect has been confirmed recently in controlled competition experiments (data not shown). These observations are not necessarily consistent with any predictions that could be made from purely descriptive data (Fig. 1). For example, significant and apparently strong competitive interactions occur between *Fimbristylis* (i) and *S. patens* (j) ($C_{ij} = 0.498$, $C_{ji} = 0.693$; see Fig. 2*d* and Table 1), species which have almost complete distributional overlap in the high marsh (compare with Fig. 1). However, little interaction is indicated between *S. patens* and *Uniola* ($C_{ij} = -0.028$, $C_{ji} = -0.078$; see Fig. 2*a* and Table 1) which have a similar distribution in the dune (Fig. 1). Again, from Fig. 1, the pattern of distributional overlap in the swale between *Muhlenbergia* and *S. patens*, *Hydrocotyle*, *Solidago*, *Andropogon*, *Paspalum* and *Eragrostis*, varies continuously from inverse to broadly overlapping, yet significant interactions are revealed between *Muhlenbergia* and at least two of the six associated species ($C_{ij} = 0.055$, 0.085, 0.130, 0.085, 0.065 and 0.100, respectively; see Fig. 2*c* and Table 1). Species interactions are abundant, but the way in which they structure these plant communities and lead to the zonation patterns observed in Fig. 1 is complex.

The interactions found were both specific and diffuse. We can quantify these based on the equitability of responses among j species to the removal of a particular species i. A high equitability would indicate diffuse interactions whereas a low equitability would indicate species-specific effects. Using the standard Shannon information measure[23], equitability $E_i = H_i/H_{\max}$, where

$$H_i = -\sum_{i=1}^{s}\left(N_{ij}/\sum_{i=1}^{s}N_{ij}\right)\ln\left(N_{ij}/\sum_{i=1}^{s}N_{ij}\right),$$

s = number of j species coexisting with i, and $H_{\max}$ is equal to H_i calculated assuming that all N_{ij} values are equal. In the high

SE, standard error of responses are based on combined error variation: within block mean square and block × treatment mean square. C_{ij} values were determined from back-transformed N_i and N_{ij} values.

* Mean cover values (after square root $(x+0.1)$ transformation) for control and removal treatment.

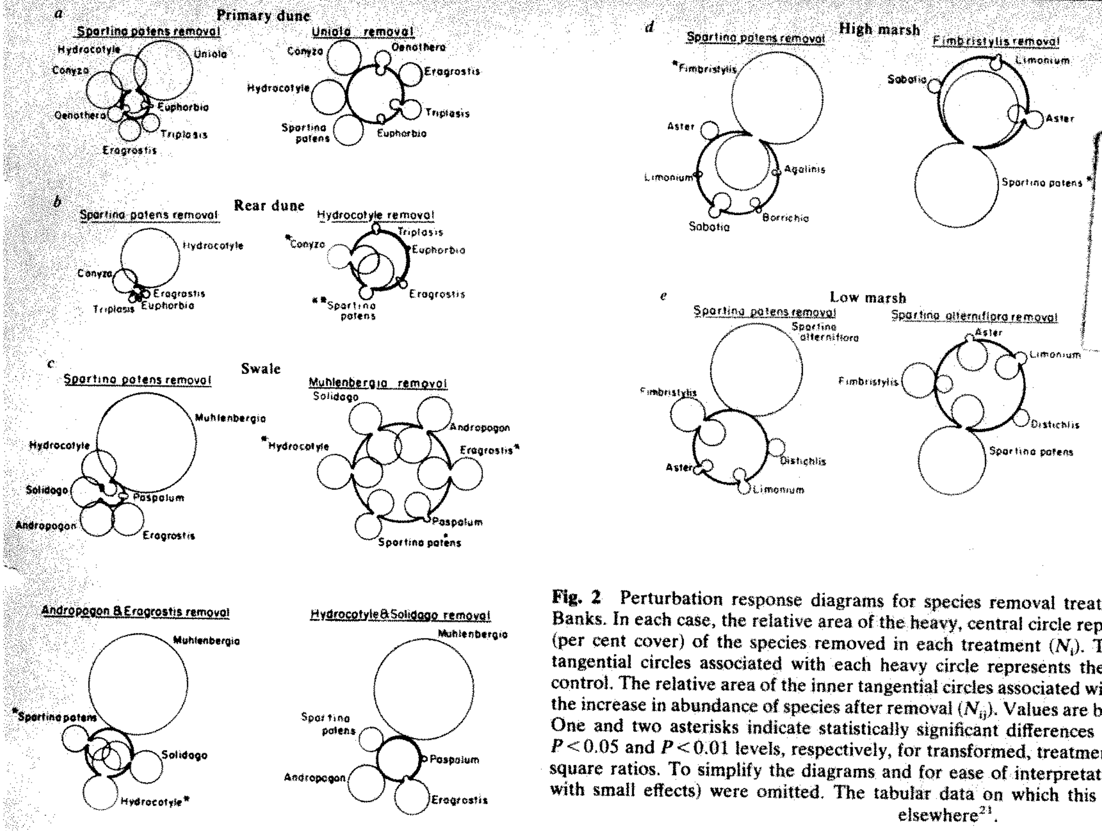

Fig. 2 Perturbation response diagrams for species removal treatments at five sites from Core Banks. In each case, the relative area of the heavy, central circle represents the relative abundance (per cent cover) of the species removed in each treatment (N_i). The relative area of the outer, tangential circles associated with each heavy circle represents the abundance of species in the control. The relative area of the inner tangential circles associated with each heavy circle represents the increase in abundance of species after removal (N_{ij}). Values are based on untransformed means. One and two asterisks indicate statistically significant differences compared with the control at $P<0.05$ and $P<0.01$ levels, respectively, for transformed, treatment and block × treatment mean square ratios. To simplify the diagrams and for ease of interpretation, negative N_{ij} values (most with small effects) were omitted. The tabular data on which this figure is based are presented elsewhere[21].

4 NOV [illegible]

marsh, removal of *S. patens* produced a large and significant response from *Fimbristylis* alone among six competitors ($E_i = 0.225$, for 4 of 6 competitors as listed in Table 1, Fig. 2*d*; absolute N_{ij} values were used). This contrasts with the swale where there were more nearly equal interactions among the six subdominant species after removal of *Muhlenbergia* ($E_i = 0.978$; Fig. 2*c*).

Non-reciprocal responses seem common across these sites. We can define reciprocity of species i with j as $R_{ij} = C_{ij}/C_{ji}$, where $\|C_{ij}\| < \|C_{ji}\|$. In four of the five sites the interactions between the dominant and subdominant species were largely non-reciprocal. In the rear dune and low marsh, $R_{ij} = -0.064$ and -0.813, respectively, for *Hydrocotyle* with *S. patens* and *Spartina alterniflora* with *S. patens* (Fig. 2). Negative values would result from non-reciprocal contraction of species j in response to the removal of species i. In the swale the dominant *Muhlenbergia* was consistently involved in non-reciprocal responses with the three subdominant components: *S. patens*, *Andropogon* plus *Eragrostis*, and *Hydrocotyle* plus *Solidago* ($R_{ij} = -0.010$, -0.171 and -0.354, respectively; Fig. 2*c*). In the primary dune, *S. patens* and *Uniola* both showed little interaction but $R_{ij} = -0.359$ (Fig. 2*a*). Only in the high marsh were the responses relatively reciprocal between *S. patens* and *Fimbristylis*, $R_{ij} = 0.719$ (Fig. 2*d*).

Site-specific effects were also prevalent. The nature, degree and reciprocity of significant species interaction between *Hydrocotyle* and *S. patens* changed depending on the habitat considered: C_{ji} for the primary dune $= 0.857$; C_{ij} and C_{ji} for the rear dune were 0.344 and -5.409, respectively; and C_{ij} and C_{ji} for the swale (*Solidago* included with *Hydrocotyle* in i) were -0.003 and 3.787 (Fig. 2a–c). Similarly the interactions of *S. patens* with *Fimbristylis* changed for high compared with low marsh ($C_{ij} = 0.498$ and 0.072; Fig. 2*d*, *e*). We cannot distinguish whether these site-specific effects are a direct effect of the environment on the species interaction, or the result of changes in background species composition, or both.

One major problem in assessing species interactions by perturbation–response studies is that the results may be time-specific and biased towards fugitive species. However, we do not believe this is applicable to the present study. The complete removal treatments allowed us to identify *Sabatia*, *Salicornia*, *Triglochin* and *Setaria* as fugitive species because they were either absent or persisted at low frequency in the community and expanded following complete removal[21]; only one of these species was found in one of the partial removal treatments. These results show that while our observations were time specific, they were not necessarily biased towards fugitive species. Clearly one could quantify fugitivity of a species by observing the change in its C_{ij} with time; however this was not done in the present study.

This experimental approach, with the associated parameters, could be extended to the level of the entire community if all species were reciprocally removed. We could then examine interference among coexisting species across the community by considering a C_{ij} matrix[24], where the elements are removal response coefficients indicating covariation in abundance of species i and j. Sets of covarying species can then be identified, and may be considered to constitute guilds[25]. Moreover, the parameters relating to diffuseness and reciprocity of the interactions can be extended, by simple weighting, to the entire community, and can then be used for comparisons between different communities, or among different classes of species (based on, for example, abundance, life form or breeding system) within particular communities. By performing single species and multi-species removals, the existence of higher order community interactions can also be tested. We have deliberately avoided interpreting C_{ij} in explicit biological terms: for example, C_{ij} could be thought of as representing the degree of overlap in resource utilization of species j on species i, but this is a presumption not warranted by either the nature of this study or any other perturbation experiment *per se*. Even if we excluded interaction effects due to predators or pathogens, deriving competition coefficients from such perturbation responses would require an *a priori* assumption as to the appropriateness of the competition model used to make such calculations.

Clearly, the information about community structuring gained from such perturbation experiments is far greater and more accurate than any inferences that might be made from purely descriptive studies. Such experiments provide a definitive test of interference among community components; the nature of this interference can then be tested either by constructing synthetic communities in controlled conditions, or by further field experimentation. Above all, when perturbation responses are quantified using the indices suggested here, they can be used in a comparative way, to generate and test hypotheses regarding the manner in which different communities are organized.

It has been shown that the establishment of urinary tract infection by *Escherichia coli* is dependent on attachment of the bacteria to epithelial cells[1–4]. The attachment involves specific epithelial cell receptors, which have been characterized as glycolipids[5–10]. Reversible binding to cell-surface mannosides may also be important[4,11–13]. This suggests an approach to the treatment of infections—that of blocking bacterial attachment with cell membrane receptor analogues. Using *E. coli* mutants lacking one or other of the two binding specificities (glycolipid and mannose), we show here that glycolipid analogues can block *in vitro* adhesion and *in vivo* urinary tract infection.

Table 1 lists the properties of the *E. coli* strains used. *E. coli* HU 824 and HU 742 were selected after a two-step chemical mutagenesis of *E. coli* GR 12, isolated from a patient with acute pyelonephritis, as having either surface ligands attaching to epithelial cells through globoseries glycolipid receptors or mannose-reversible binding properties. The mutants HU 742 and HU 824 were obtained after *N*-methyl-*N*-nitro-*N*-nitrosoguanidine treatment of a lactose-negative mutant of GR 12. Further details on the construction and stability of the mutants will be reported elsewhere[14]. The mutants and the parent were identical by the following genotypic and phenotypic characteristics available for testing: electrophoretic mobility of 13 chromosomally determined enzymes[15], three plasmid bands of the same size[16], serotype[17], resistance to the bactericidal effect of serum[18], inability to haemolyse horse erythrocytes[17] and api 20 E pattern. Clearly, these tests or other techniques are insufficient to demonstrate genetic identity between the mutants. The only discernible difference between these strains was, however, the receptor specificity of their adhesins. Initially,

Table 1 Properties of the *E. coli* strains HU 824 Str^R and HU 742 Nal^R, used for experimental ascending urinary tract infection

Property	*E. coli* strain HU 824 Str^R	 HU 742 Nal^R

Agglutination of guinea pig erythrocytes		
Uncoated in PBS	−	+
in α-Mn	−	−
Coated with globotetraosylceramide		
in PBS	+	+
in α-Mn	+	−

E. coli HU 824 and HU 742, mutants of a wild-type pyelonephritogenic *E. coli* strain, were identical for the genotypic and phenotypic traits listed, but differed in specificity of their adhesins. R, resistant; S, sensitive; Knt, nontypable for Kantigens[17]. To permit separate detection out of a mixture, mutants resistant to 1 mg ml^{-1} of streptomycin (HU 824 Str^R) or to 50 μg ml^{-1} of nalidixic acid (HU 742 Nal^R) were selected by the gradient plate technique (without mutagenesis). The resistant mutants grew equally well on TSA with or without antibiotic after passage on antibiotic-free medium, retained the adhesive and haemagglutinating properties and showed no difference in *in vivo* infectivity compared with the respective parent. Adhesion to uroepithelial cells from the urinary sediment of a healthy female donor (blood group P_1) and the bladder of BALB/c mice was assessed as described elsewhere[1–3]. Adhesion = mean no. of bacteria attached to 40 epithelial cells. For adhesion inhibition, bacteria were preincubated with decreasing concentrations of globotetraose or αMn, epithelial cells were added and adhesion testing was performed[5,7]. The concentration required for 50% inhibition of the adherence of 10^9 bacteria is shown. NI, no inhibition. Induction of binding of *E. coli* HU 824 Str^R was studied by agglutination of guinea pig erythrocytes coated with globotetraosylceramide[5,6]. Agglutination after but not before coating, and in the presence of αMn, was credited to the receptor. The oligosaccharide globotetraose, released from globoside by ozonolysis, and purified by Folch partitioning and alkaline fragmentation, was analysed by gas-liquid chromatography and NMR (ref. 23). The NMR spectroscopy in D_2O spectrum showed signals from three anomeric protons with chemical shifts, as expected for globotetraose: β-hexoseamine, β-hexose and α-hexose. The fourth anomeric signal from the reducing glucose residue was split into two, corresponding to the α and β form in the proportions 1:2.

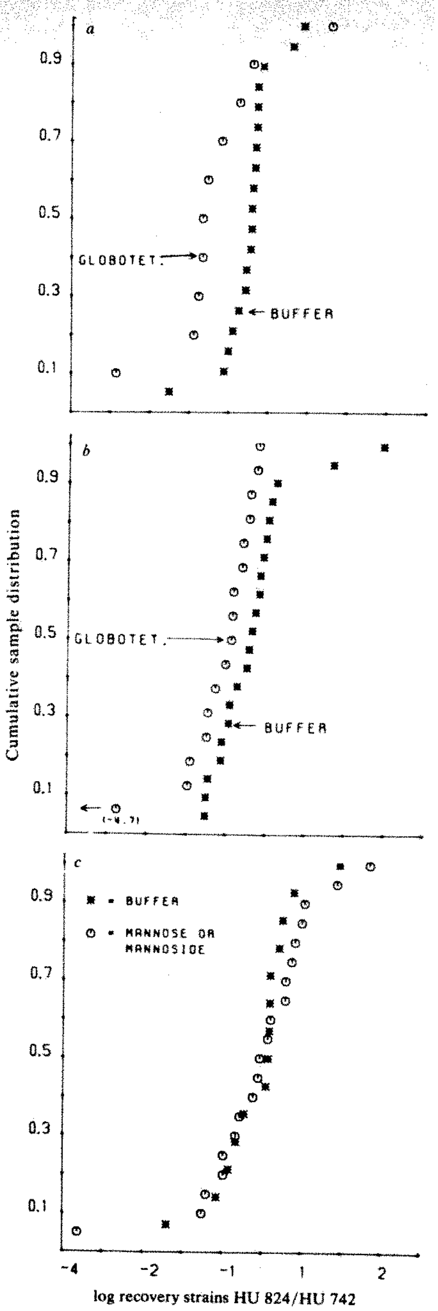

Fig. 1 Recovery of *E. coli* HU 824 Str$^{\rm R}$ and HU 742 Nal$^{\rm R}$ in the presence and absence of receptor sugar. The strains were grown on antibiotic-free media, collected into PBS with globotetraose (50 μg ml^{-1}) for expt 1 and 30 μg ml^{-1} for expt 2, which were, respectively, four and three times the *in vitro* IC$_{50}$ for *E. coli* HU 824) or into PBS with αMn (5 mg ml^{-1} for both experiments which was 50 times the IC$_{50}$ of HU 742 *in vitro* adhesion), and incubated for 60 min at 37 °C. Viable counts on the inoculum before and after incubation excluded changes in bacterial numbers due to the presence of the sugars. The inocula (per animal) for expt 1 were: PBS, $3.9\times10^8+8.3\times10^7$; globotetraose, $9.7\times10^7+8.3\times10^7$. For experiment 2: PBS, $3.0\times10^8+3.9\times10^7$; globotetraose, $2.9\times10^8+3.3\times10^7$ of HU 824 Str$^{\rm R}$ and HU 742 Nal$^{\rm R}$ respectively. The inocula per animal for the αMn experiments were for expt 1: PBS, $2.3\times10^9+1.4\times10^8$; αMn, $3.7\times10^9+1.1\times10^8$. For expt 2: PBS, $6.4\times10^8+8.3\times10^7$; αMn, $4.4\times10^8+1.0\times10^8$ of HU 824 Str$^{\rm R}$ and HU 742 Nal$^{\rm R}$ respectively. The mixed inocula with or without receptor sugar were injected into the bladder of mice which were killed 2 or 16 h later. Serial dilutions of the homogenized kidneys and bladders were cultured on TSA (BBL, Cockeysville, Maryland), TSA streptomycin (1 mg ml^{-1}) or ISA nalidixic acid (50 μg ml^{-1}). The relative recovery from each animal and tissue of the two strains is given as log (RHU 824/RHU 742). The cumulative sample distribution[24] of the recovery ratio is presented, starting from the animal with the lowest recovery and adding up to all animals (=100%). Both in kidneys (a) and bladders (b) a significant shift towards lower recovery of HU 824 Str$^{\rm R}$ was observed after globotetraose treatment. No significant effect of αMn treatment was observed (c). The differences obtained with globotetraose were significant both at 2 and at 16 h, and the results from these animals have been pooled.

the two strains had identical antibiotic resistance patterns. To allow separate detection from a mixed inoculum, mutants resistant to 1 mg ml^{-1} of streptomycin (HU 824 Str$^{\rm R}$) or to 50 μg ml^{-1} of nalidixic acid (HU 742 Nal$^{\rm R}$) were selected (see Table 1 legend).

The difference in receptor specificity between the adhesins of *E. coli* HU 824 Str$^{\rm R}$ and HU 742 Nal$^{\rm R}$ was characterized by adhesion inhibition by soluble receptor sugars or induction of binding to previously unreactive cells by receptor coating[5–7] (Table 1 legend). The adhesion to human uroepithelial cells of 10^9 *E. coli* HU 824 Str$^{\rm R}$ was reduced to 50% by 9 μg ml^{-1} of globotetraose, the oligosaccharide obtained from globoside (a receptor glycolipid) by ozonolysis[19] (Table 1 legend). *E. coli* HU 742 carried mannose-binding adhesins defined by mannose-reversible agglutination of guinea pig erythrocytes[21]. The adhesion of *E. coli* HU 742 Nal$^{\rm R}$ to human or mouse epithelial cells was inhibited by α-methylmannoside (αMn), although inhibition was too low to allow exact determination of the 50% inhibitory αMn concentration (IC$_{50}$). Association with urinary slime[13] could not be assayed quantitatively. The agglutination by *E. coli* HU 742 of guinea pig erythrocytes was inhibited by αMn both before and after coating with globoside. *E. coli* HU 824 Str$^{\rm R}$ agglutinated guinea pig erythrocytes after, but not before globoside coating. This reaction was unaffected by αMn.

Female BALB/c mice, aged 6–8 weeks, were infected by catheterization of the urethra and injection of 0.05 ml of a bacterial suspension (L.H. *et al.*, in preparation). The animals were killed at various times later, kidneys and bladders homogenized and viable counts performed. It was soon recognized that the high degree of variation among animals in the recovery of *E. coli* from kidney or bladder would tend to mask moderate differences between experimental and control groups. For this reason, each mouse was infected with a mixture of *E. coli* HU 824 Str$^{\rm R}$ and HU 742 Nal$^{\rm R}$, separable from the mixture by their different antibiotic resistance. At the end of an experiment, kidneys and bladders of each animal were homogenized separately, and quantitative cultures of each strain prepared on agar plates containing the appropriate antimicrobial agent. The recovery, R, of a given strain was then determined as R = no. of bacteria in the organ cultured/no. of bacteria in the inoculum.

To evaluate the *in vivo* effectiveness of a given treatment (for example, the addition of globotetraose or αMn to the inoculum), the two *E. coli* strains were chosen such that one was susceptible and the other resistant to the *in vitro* effects of the treatment under test. The *in vivo* effectiveness of the treatment was then evaluated by comparing the recoveries of the two strains as the recovery ratio, R (susceptible)/R (resistant). Consequently, if the recovery ratio in the experimental group was significantly lower than in the control group, it could be concluded that the treatment had been effective *in vivo*. In this manner, the randomizing effects of individual differences among animals were overcome by having one *E. coli* strain serve as an intrinsic control in each animal.

Inocula consisting of *E. coli* HU 824 Str$^{\rm R}$ and HU 742 Nal$^{\rm R}$ were prepared as detailed in Fig. 1 legend. After incubation with globotetraose or αMn, respectively, the *in vitro* attachment to mouse epithelial cells and agglutination of human or guinea pig erythrocytes was abolished. The inocula in phosphate-buffered (saline PBS) retained these properties. After intravesicular injection of the inocula, the animals were killed and viable counts of the homogenized kidneys and bladders on trypticase soy agar (TSA), TSA-streptomycin or TSA-nalidixic acid were performed. The result of globotetraose treatment is shown in Fig. 1a for kidney cultures and in 1b for bladder cultures, while Fig. 1c shows the result of αMn treatment. The recovery of *E. coli* HU 824 Str$^{\rm R}$ was significantly reduced, both in kidneys and bladders after globotetraose treatment, as seen by the shift of the cumulative sample distribution curve towards the left ($P=0.019$, Mann–Whitney U-test). After αMn treatment the opposite effect, a decrease of HU 742 Nal$^{\rm R}$ recovery with a shift of the cumulative sample distribution to the right, might have been expected. No significant difference from the PBS control was observed.

We propose the following interpretation of the results. Capacity to attach to the mucosal lining of the mouse urinary tract was an important survival mechanism for *E. coli* HU 824, as seen by its efficient adherence to mouse bladder cells *in vitro* and the decrease of *in vivo* infectivity after pretreatment with globotetraose. *E. coli* HU 742 attached in low numbers *in vitro* to the mouse bladder cells, but might bind to urinary slime. An inhibitory effect of αMn *in vivo*, as reported in other systems[20], may be masked by a dual effect of αMn. Blocking of binding to mucus may facilitate the ascent of bacteria to the kidney, as well as increase the elimination of bacteria from the urinary tract. The inhibition of experimental infection by globotetraose, on the other hand, illustrates a new approach to prophylaxis and treatment of infections occurring via mucous membranes. Compounds mimicking the host receptors may competitively bind to bacterial surface ligands[20,22]. This might decrease the number of bacteria attaching to the mucosa sufficiently to alter the delicate balance of host-parasite interaction in favour of the host.

This study was supported by grants from the Swedish MRC (projects 215 and 3967, 6034), the University of Göteborg, the Ellen, Walter and Lennart Hesselman Foundation for Scientific Research, the Swedish Board for Technical Development and the Volkswagen Foundation. C.S.E. was supported by a Fogarty Fellowship (018497). The BALB/c mice were purchased from Dr B. Murphy. Mutant construction and the cloning of the pilus genes were performed in the laboratory of S. Falkow, University of Washington, under NSF grant PCM 8015722 and NIH grant AI 10885-07. S.H. was a trainee under NIH grant 07149-02. R.H. was a fellow of NKF and the NIH.

A stem cell for stem cells in murine haematopoiesis

D. I. Burton, J. D. Ansell, R. A. Gray & H. S. Micklem

Department of Zoology, University of Edinburgh,
Edinburgh EH9 3JT, UK

Mature erythrocytes and granulocytes have limited lifespans, do not replicate and must therefore be replenished constantly. They are derived from pluripotent stem cells (PSCs) which are capable of self-renewal[1]. The numbers and properties of PSCs can be inferred in part from studies of their progeny. Such studies have depended largely on highly artificial experimental systems, involving such procedures as X-ray irradiation, bone marrow transplantation and parabiosis[2]. We now describe a method for studying the behaviour of haematopoietic cell populations in normal mice, and show that erythropoiesis is maintained by the products of a very small number of clones which, as predicted by Kay[3], arise and decline in succession. These results suggest that spleen colony-forming cells (CFC), usually regarded as stem cells, are themselves members of substantial clones which differentiate in sequence.

In female mammals, one of the two X chromosomes becomes irreversibly inactivated early in embryogenesis; subsequently any somatic cell and its descendants fail to express genes carried on the inactivated chromosome[4,5]. X-linked genetic variants can therefore provide markers for cell population studies, and have been used to estimate embryonic founder cell numbers for the haematopoietic system[6,7]. Recently, the discovery of an electrophoretic variant of the X chromosome-encoded enzyme phosphoglycerate kinase (PGK-1)[8], and the development of improved methods for measuring PGK activity in electrophoresis strips[9], have provided a convenient marker system in the mouse.

Female mice heterozygous at the PGK-1 locus were bled at 14-day intervals for 16 weeks and then at 28-day intervals for a further 40 weeks. The enzyme phenotypes were determined electrophoretically from haemolysates using a modification of the technique of Bücher *et al.*[9].

The percentages of PGK-1A alloenzyme in serial blood samples from 10 normal heterozygous mice are shown in Fig. 1. Large, and frequently sudden, variations in the relative amounts of A and B alloenzymes are evident in every individual,

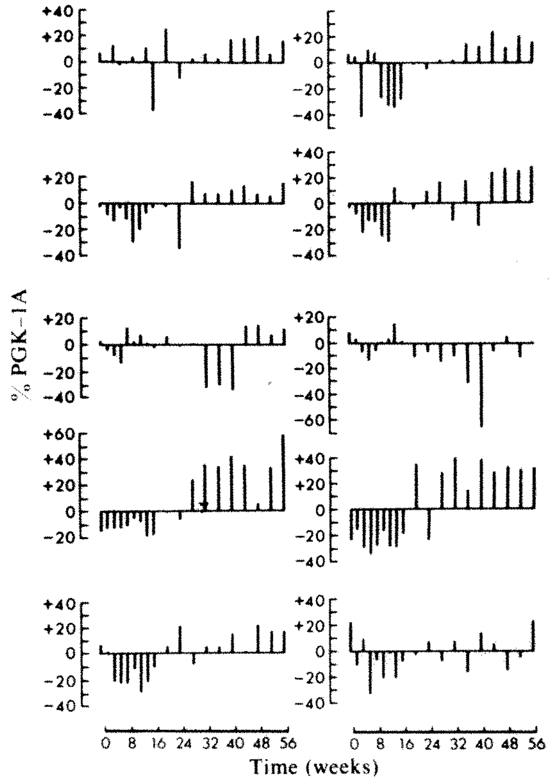

Fig. 1 Percentages of PGK activity attributable to the A alloenzyme in serial blood samples from 10 PGK-1A/B heterozygous female mice. The data for each mouse are plotted as the deviation of individual samples from the overall percentage of A alloenzyme in the mouse; this was estimated as the mean of the readings obtained on day 0 and at 56-day intervals thereafter (see text). The percentages of A and B alloenzymes were determined electrophoretically from haemolysates as described by Bücher *et al.*[9], with the following modification. After electrophoresis, the Cellogel electrophoresis strips were applied to a polyethylene imine (PEI) TLC sheet on which had been spread a solution of the enzymes, substrates and co-factors necessary for the visualization of PGK activity[9], with added ^{14}C-labelled D-glucose. The radioactive final products of the linked enzyme reactions (glucose-6-phosphate and 6-phosphogluconolactone) were adsorbed onto the PEI sheet[14], which was then autoradiographed on Kodak XS X-ray film. The autoradiographs were scanned with a double-beam recording densitometer and the area under each peak integrated. The figures obtained were corrected to compensate for the log-linear response of the X-ray film to exposure, as determined by calibration with a series of known alloenzyme mixtures, and the proportions of the A and B alloenzymes were calculated. In most animals the overall A:B ratio was $\sim$7:3, a value consistent with the expected linkage of *xce* alleles (controlling the probability of a given X chromosome excaping inactivation) to the PGK-1A and 1B alleles[15]. The mice used were from the eighth generation back-cross of PGK-1A onto the CBA/Ca (PGK-1B) strain.

0028-0836/82/310562—02$01.00

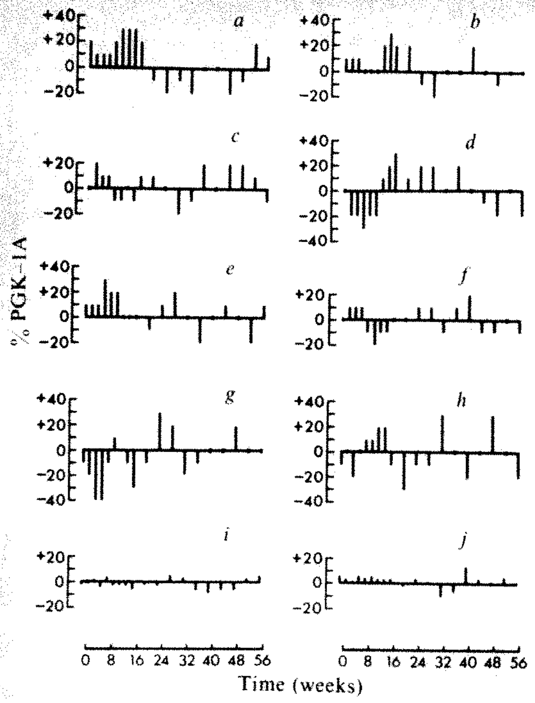

Fig. 2 Computer simulations of PGK phenotypes in serial blood samples, generated on the assumptions that (1) erythrocyte lifespan = 45 days; (2) PGK-1A and 1B-expressing clonogenic cells are selected at random; and (3) each clone produces erythrocytes for only a limited period before becoming extinct or quiescent. Three (*a–h*) or 15 (*i*, *j*) clones productive over any 14-day period. The simulations shown are unselected, i.e. first series generated.

suggesting that only a few clones of cells are represented in each blood sample and that the identity of these can change rapidly. On the simplifying assumption that all erythropoietic clones are of equal size, the number of clones (n) can be estimated by the binomial equation $n = p(1-p)/s^2$ (refs 10, 11) where p is the best estimate of the overall proportion of A alloenzyme in the haematopoietic system, calculated as the mean from several blood samples; $1-p$ is the proportion of B alloenzyme; and s^2 is the variance of individual and independent samples around p. As the lifespan of erythrocytes in the mouse is ~40–45 days[12], blood samples taken at 14- and 28-day intervals are not independent and therefore cannot all be used to estimate p and s^2. Accordingly, n was calculated from the samples taken at day 0 and at 56-day intervals thereafter. The mean value of n was 10 and the range 2–30. This wide estimated range is largely due to statistical error, as only eight independent blood samples were obtainable over the 56-week period of the study. Using the value 10, and assuming 10^{10} erythrocytes per ml of blood with a blood volume of 2 ml, each clone must average 2×10^9 erythrocytes and is therefore large enough alone to provide the total steady-state erythrocyte requirements for 4.5 days; three clones could provide for 14 days. The large changes that can occur in A : B ratios within 14 days suggest that clones do indeed arise and decline in quite rapid succession. Computer simulations of our data, assuming that three clones maintain the whole burden of erythropoiesis for 14 days and then cease production, are shown in Fig. 2(*a–h*). These simulations correspond quite closely to the actual data, while simulations using any substantially larger number of clones—for example 50 in a blood sample, corresponding to 15 over a 14-day period—do not generate sufficient variability (Fig. 2*i–j*).

To make a clone of 2×10^9 cells requires a production line of 31 doublings, which is far longer than has been estimated for the production of erythrocytes from CFC—about 12–14 doublings[13]. CFC have long been regarded as haematopoietic stem cells and some of them at least have the stem cell properties of self-renewal and pluripotency. Our data show that those CFC which undergo erythroid differentiation are themselves substantial clones, separated by 17–19 doublings from the clonogenic cell, and that these clones are used sequentially to maintain erythropoiesis.

This work was supported by the Melville Trust and by the MRC, of which D.I.B. is a research student. We thank Dr J. D. West for the gift of our initial breeding stock of PGK-1A mice

Analysis of fibroblast proteins from patients with Duchenne muscular dystrophy by two-dimensional gel electrophoresis

E. Rosenmann, C. Kreis, R. G. Thompson, M. Dobbs, J. L. Hamerton & K. Wrogemann

Departments of Biochemistry and Pediatrics (Genetics),
University of Manitoba, Winnipeg, Canada R3E OW3

Duchenne muscular dystrophy (DMD), the most common and severe form of the muscular dystrophies, is an X-linked inborn error of metabolism with multiple tissue involvement. Although the major pathological changes are observed in skeletal muscle, abnormalities have also been detected in the heart[1], nervous system[2], red blood cells[3], lymphocytes[4] and cultured skin fibroblasts[5–7]. For many reasons, such as readily available tissue material, fewer secondary changes and the potential for prenatal diagnosis, cultured skin fibroblasts should be the tissue of choice to search for the primary defect. Several abnormalities have been reported in DMD fibroblasts, suggesting that the genetic abnormality is expressed in these cells[5–7]. To search for potentially mutant protein(s) we have compared the protein composition of normal and DMD fibroblasts by two-dimensional gel electrophoresis and have now found one protein spot consistently missing in DMD cells. The nature of this protein and its relation to the DMD gene are unknown.

Genetic alterations responsible for a disease are generally reflected in specific proteins which could be structurally altered, synthesized in abnormal quantities or not made at all. We have searched previously for mutant proteins in DMD fibroblasts using one-dimensional polyacrylamide gel electrophoresis in combination with a dual labelling technique and found no consistent abnormality[8]. This indicated that the most abundant proteins in fibroblasts are not affected by the DMD gene. With the development of two-dimensional polyacrylamide gel electrophoresis[9], the power of resolution for protein composition was greatly improved. However, using the O'Farrell technique[9] we encountered problems in obtaining absolute consistency between the protein maps of separate experiments. We therefore used a dual labelling approach, in which normal and DMD cells are labelled with two different isotopes (^{14}C- and ^{3}H-leucine), mixed and then co-electrophoresed on the same gel.

0028-0836/82/310563—03$01.00

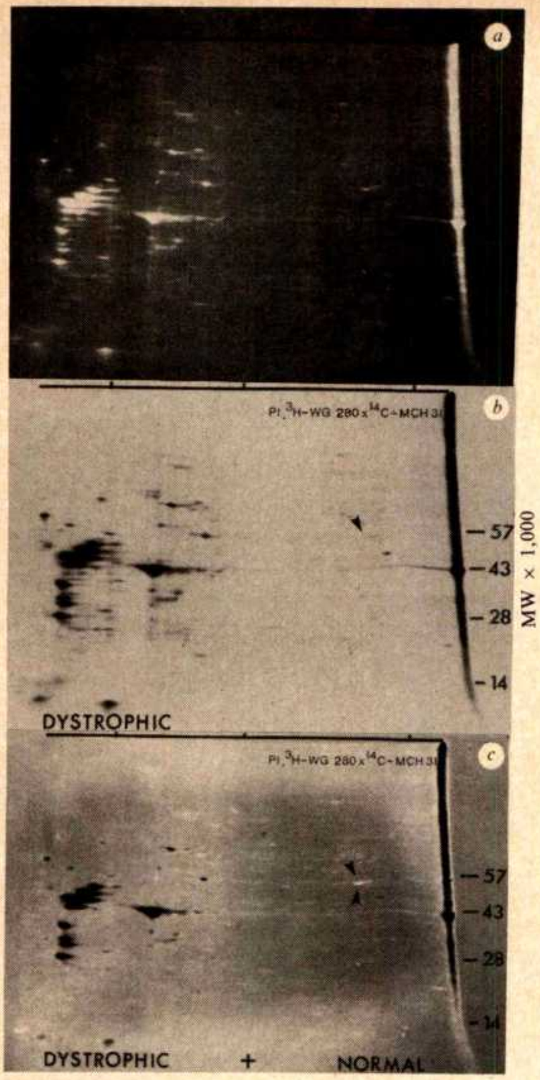

Fig. 1 Analysis of protein composition of normal and dystrophic human fibroblasts by two-dimensional gel electrophoresis in combination with double-label autoradiography[10]. *a*, The negative of an autoradiogram (to give white spots) showing protein spots from normal cells; *b*, a fluorogram showing the protein map of dystrophic cells. The arrows indicate a protein spot of M_r 56,000 and a pI of ~6.7 present in normal cells (*a*) but not in dystrophic cells (*b*). *c*, A superimposition of *a* and *b*. White spots (normal) identical to black spots (dystrophic) are covered by this procedure. The 56 K spot indicated by arrows is not covered. Cells were seeded in 60-mm Petri plates at a concentration of 1×10^5 cells per plate in McCoy's medium (10% in fetal calf serum, FCS) and grown at 37 °C for 14 days, at which time they were always confluent. Media were changed twice weekly. For labelling, the medium was replaced with 1.5 ml of a similar medium containing 36.3% FCS and either 1 mCi of [4, 5-^{3}H]leucine or 25 μCi of [U-^{14}C]leucine (Amersham) and the cells were labelled for 48 h at 37 °C. In some experiments, cells were seeded in 100-mm plates and conditions were adjusted accordingly. Cell lysates were prepared according to O'Farrell[9]. For isoelectric focusing (IEF) the lysates from normal and dystrophic fibroblasts were combined in a ratio of 400:1 ^{3}H d.p.m. to ^{14}C d.p.m. Two-dimensional electrophoresis was performed according to O'Farrell[9] with minor modifications. IEF gels were prepared using 0.4% pH 3.5–10 and 1.6% pH 5–7 ampholines (LKB) and polymerized in glass rods 12.5 cm long and 3 mm in diameter. A sample consisting of ~200 μl of radioactive cell lysate containing ^{3}H-labelled and ^{14}C-labelled protein and ~100 μg of total protein was applied to each gel. With every double-labelled gel, a control gel was run which only contained ^{14}C-labelled proteins. IEF was carried out for 16 h at 400 V followed by 45 min at 800 V for a total of 7,000 V h. Electrophoresis in the second dimension was done in slab gels 0.75 mm thick with an 8–14% exponential gradient of acrylamide. The IEF gel was applied to the second dimension with or without prior freezing and was not equilibrated. After completion of electrophoresis, gels were fixed and prepared for fluorography by standard procedures. For double-label autoradiography, the procedure of Walton *et al.*[10] was followed. Gels containing double-labelled material and gels containing ^{14}C-labelled material, in the same amount as that of the double-labelled gels, were prepared for fluorography. Exposure of the fluorograms to X-ray film showed that there was no spillover of ^{14}C-labelled material during ^{3}H exposure except for the most prominent spots. To determine the pH of the gradient formed in the first dimension, a parallel IEF gel containing unlabelled protein from normal fibroblasts was extruded and rapidly sliced into 10-mm sections. Each section was then equilibrated in capped tubes containing 0.5 ml of water per tube. Molecular weights were determined on the second dimension by the use of appropriate markers. The photographs show the protein pattern of homogenates of normal and dystrophic fibroblasts which were mixed and electrophoresed on the same IEF gel. In this experiment (pair 1 of Table 1) the dystrophic fibroblasts were labelled with ^{3}H-leucine. The normal fibroblasts were labelled with ^{14}C-leucine.

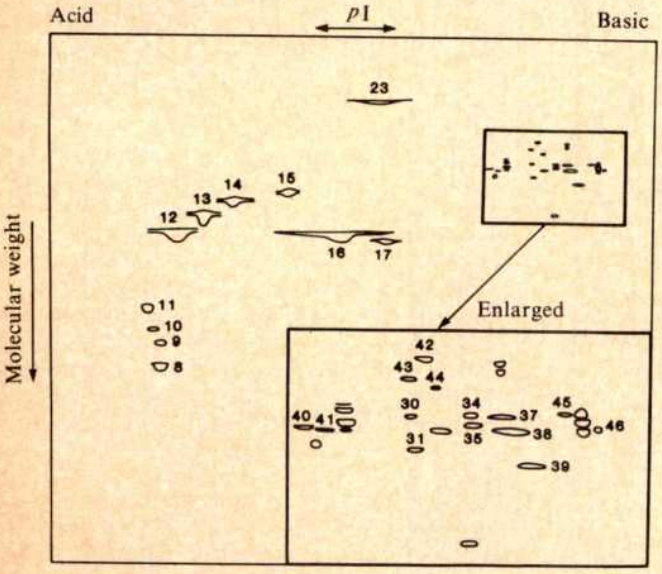

Fig. 2 Diagram of spots cut out from a two-dimensional gel for analysis by liquid scintillation counting. Cells from the normal strain MCH 40 labelled with [4, 5-^{3}H]leucine were combined with cells from the DMD strain DC (male, 13 yr, Department of Pediatrics, Winnipeg) labelled with [U-^{14}C]leucine and co-electrophoresed essentially as in Fig. 1, except that the acrylamide concentration of the second dimension was 10%. The gel was silver stained[11] and the spots indicated were cut out for dual label liquid scintillation counting[13]. Spot no. 35 corresponds to the 56 K/6.7 protein of Fig. 1. Additional spots were cut out to provide a reliable mean ratio of ^{3}H/^{14}C for reference (see Fig. 3).

Whether protein spots come from normal and/or dystrophic cells is determined by dual label autoradiography[10] which produces two superimposable X-ray films: one shows only ^{3}H-labelled spots, the other only ^{14}C-labelled spots.

With this technique we detected numerous differences between normal and DMD fibroblast proteins (Table 1) but only one difference was seen consistently: the absence in DMD of a protein spot of molecular weight (M_r) ~56,000 (56 K) with an approximate isoelectric point of 6.7 (Fig. 1). This abnormality was seen in fibroblasts from six different patients with DMD, which were compared with six control strains in eight different combinations. The protein spot was missing irrespective of whether the dystrophic cells were labelled with ^{3}H-leucine or ^{14}C-leucine (Table 1). In two pairs, overexposure of the fluorography for tritium (dystrophic cells) did not reveal a spot, although extreme overexposure will always reveal a spot due to ^{14}C-leucine from the normal cells.

A problem was encountered with pair 6 (Table 1): based on the constellation of spots in the 56 K/6.7 area it appears that both normal and dystrophic cells do not have the 56 K/6.7 protein. However, an extra spot of the same apparent molecular weight was seen at an approximate pI of 6.5 in normal cells. We are now exploring the hypothesis that this spot represents a variant of the normal 56 K/6.7 protein.

Some of the autoradiograms of the dual-label study had to be exposed for over 6 months. However, three more rapid techniques were successfully used to confirm our original findings (to be published elsewhere in detail). The absence of the 56 K/6.7 protein spot in DMD cells was also detected when the cell strains were labelled with ^{35}S-methionine or when unlabelled proteins were visualized by a sensitive silver staining method[11]. Furthermore, when silver-stained spots from gels containing dual-labelled samples of an additional pair of normal

MCH and WG cell strains were obtained from the Repository for Mutant Human Cell Strains, Montreal, Canada; MW and JB from the Department of Pediatrics (Genetics), University of Manitoba, Winnipeg, Canada. All cell strains were from male individuals, matched closely for passage number and were used at passage 18 or less. The position of protein spots is given in approximate coordinates of $M_r \times 1{,}000/pI$. These coordinates have to be considered gross approximations, as no internal markers for M_r and pI were included in the experiments.

and dystrophic cells were excised (Fig. 2) and their radioactivity determined by liquid scintillation counting, the 56 K/6.7 protein spot showed <20% of radioactivity of the isotope of DMD cells (^{14}C) as documented by the highly abnormal ratio of ^{3}H/^{14}C of spot number 35 (Fig. 3).

If the 'missing' protein described here is responsible for DMD, it should be missing in all fibroblast strains from DMD patients, unless there is genetic heterogeneity in this disease. The protein should be coded for by the X chromosome, and one should be able to show evidence for lyonization[12] in fibroblasts cloned from carriers of DMD. Experiments to test these points are in progress. At present, the nature and significance of this missing protein are not known. Whether a direct or a secondary result of the DMD gene, these findings provide further support to the hypothesis that DMD is indeed expressed in cultured skin fibroblasts and can be studied in these cells.

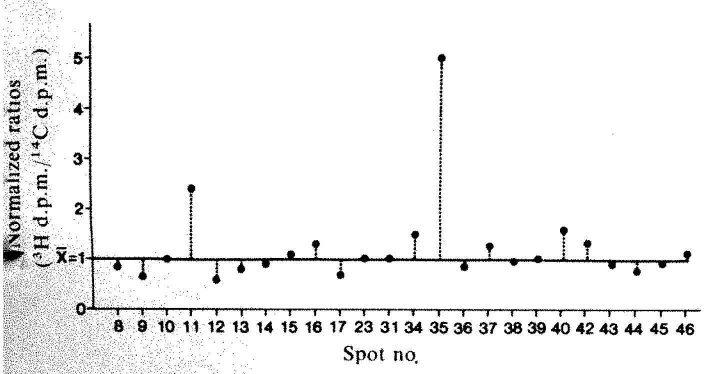

Fig. 3 Normalized ratios of ^{3}H/^{14}C d.p.m. of the protein spots designated in Fig. 2. Scintillation counting and analysis were done as described elsewhere[13,14]. The mean of the normalized ratio of all spots equals one and the dotted lines indicate the deviation from the mean.

We thank A.-M. Adachi, A. Vust, T. Trottershaw and M. LaFleur for technical assistance. This work was supported by the Muscular Dystrophy Association of Canada, the Manitoba Heart Foundation and the MRC of Canada.

The serological recognition of 'new' gene products of the *HLA* system can be accomplished by selecting sera with strong leucocyte antibodies and testing these against a panel of cells obtained from donors which are compatible for the known HLA antigens with the antibody producer. This approach, which we termed the HLA-CAP approach (compatible with antibody producer), was essential in the recognition of what is now called the *HLA-DR* locus[1] and of non HLA-linked T-cell subgroups[2]. Using the same technique, we have defined here several sera recognizing a structure on monocytes similar to one of the alleles of the HLA-linked PL3[3,4] or secondary B-cell (SB)[5,6] system, so far only recognized by cellular techniques.

Over 100 sera obtained from HLA-A1-B8-DR3 positive women which produced strong leukocyte antibodies, were tested against lymphocyte suspensions obtained from HLA-A1-B8-DR3 homozygous individuals. The two colour fluorescence (TCF) technique[7] was used, which allows the recognition of antibodies against B cells, T cells and monocytes independently, without the need to separate these cells. In this technique, which is a complement dependent cytotoxicity test, ethidium bromide was used as a dye for dead cells, which is a more sensitive reagent to test for viability than the eosine stain normally used.

Using these techniques, antibodies that reacted with T cell subsets were identified[2] and also a cluster of antibodies that reacted primarily with monocytes. The reaction pattern of 22 of these sera is given in Table 1. When the homozygous panel cells were tested by means of the primed lymphocyte test (PLT) for the five alleles of the recently described SB system[5], four of the sera showed an almost perfect fit with SB4 and one with SB1+4.

Because the sera also contained strong anti-HLA class I and class II antibodies they were absorbed with buffycoat cells obtained from donors which were SB4 negative so that they could be used to type a random panel of cells. After absorption the sera were tested against 25 unrelated SB typed individuals (Table 2). There is a highly significant and clearcut correlation between the SB4 determinant as recognized in PLT testing, and the antisera 37270, 35572 and 34155. However, one of the panel donors was positive with these sera, but negative for SB4 when tested with the PLT-SB4 reagents. This discrepancy may be an artefact as the SB4 is the most poorly defined allele of the SB system but it may be that SB4 as recognized in PLT is distinct from the determinant recognized by our sera. Sera were obtained from women that had HLA–A1, –B8 and DR3 determinants. These sera were tested on mononuclear cells from donors which were homozygous for HLA–A1–B8 and –DR3 in the two colour fluorescence (TCF) technique, described previously[7]. In brief, B lymphocytes and monocytes from a lymphocyte suspension obtained after Ficoll-Hypaque density gradient separation, were labelled with a goat anti-human immunoglobulin FITC conjugate. This cell suspension was used in a micro lymphocytotoxicity assay with antisera and complement. Dead cells were stained with ethidium bromide. The reading of the test was carried out with an inverted microscope containing a Ploemopak filter combination. Excitation filters: LP 455- SP 490, barrier filter: LP 520, Zeiss filter combination no. 487709). If 20–50% of the monocytes were lysed, the reaction was considered to be positive (indicated by +).

Table 2 Two-by-two comparison of SB4 with 5 different sera

SB4 serum no.	+ +	− +	+ −	− −	P*
37270	15	1	0	9	<0.0001
35572	15	1	0	9	<0.0001
34155	15	1	0	9	<0.0001
30147	15	8	0	2	0.15
1950	11	1	4	9	0.003

The relevant sera were absorbed with selected buffycoat lymphocytes which carried the HLA–A, –B, –C and /or –DR antigens corresponding to the antibodies in the sera, but lacking the SB4 determinant. The reactivity of serum 34155 with SB1 positive donors was eliminated due to absorption with SB1 positive buffycoat lymphocytes.

* Fisher's exact P value.

words, the relationship of SB and the presently described serologically defined determinant may be as confusing as the relationship between HLA–D and HLA–DR.

The husbands of the women whose sera had shown positive SB4 reactivity were tested with all the SB4 associated antisera (Table 3). These results showed that the monocytes of the women were negative with the 'anti SB4' sera, but the husbands' monocytes reacted positively. Preliminary data indicate that in this way also antibodies can be identified which react with SB1 or SB5 positive cells.

The data presented here show that it is possible to recognize a product, by serotyping on monocytes, which shows a very significant association with a product recognized by cellular (that is PLT) typing. It appears that this structure is encoded in the *HLA* region but it is not clear why this structure is detected only on monocytes. CML studies[5] suggested the presence of SB determinants on B cell lines. Moreover a monoclonal antibody, I-LR1, first described by Nadler *et al.*[8], recently has been shown to react with an epitope present on lymphocytes of SB2, 3 and a low number of SB4 positive individuals. This monoclonal antibody was reactive (as shown in an immunofluorescence technique) with a class II molecule, present on B cells, monocytes and activated T cells[8]. This observation is in contradiction to our present findings which indicate that the SB-like determinants, as recognized by serology, are primarily expressed on monocytes. There are at least two explanations for this discrepancy.[1] The determinant recognized by our sera is present on B cells as well, but for technical reasons (for example the distance of antigenic sites) the complement dependent cytotoxicity test could be negative[2]. Alternatively it could be that the determinant recognized by our sera is not expressed on B cells. Paul and coworkers[9] found a polymorphic determinant expressed on monocytes and some endothelial cells but not on B cells. Absorption studies are under way to determine whether this possibly more sensitive technique may show that the structures recognized by our sera are present on B cells.

Recent studies suggest that there may be many more loci[10,11] in the *HLA* region than those presently recognized and our results show the importance of using antibodies which react with only subsets of mononuclear cells and more sensitive techniques than those commonly used in tissue typing should be used.

We conclude that the antibodies described here recognize an epitope on a gene product which is highly associated with or identical to SB. These antibodies will enable biochemical analysis of this gene product, but will not answer the question of identity or non-identity of SB and the determinant recognized by the antibodies. As long as uncertainty exists about the identity of SB determinants recognized by cellular techniques and the determinants identified by means of serology, we suggest an independent nomenclature. Following HLA–A, –B, –C, and –D we recently described the serologically defined DR linked determinant LB–E[12] (similar to or identical with MB[13]). The presently described determinant will be referred to as LB–F. For convenience, the number indicating the allele of the LB–F system should be identical to the number of the corresponding SB allele, i.e. in our case LB–F4.

Table 3 Reactivity of the SB4 associated antisera tested against monocytes from the antibody producers and their husbands

Monocytes from the producers of serum no.	Serum no. 37270	35572	34155
37270	−	−	−
35572	−	−	−

The human hepatoma cell line PLC/PRF/5, which contains integrated hepatitis B virus DNA, synthesises and secretes hepatitis B virus surface antigen (HBsAg)[1,2]. When injected into BALB/c nude mice, these cells produce well-vascularized, encapsulated tumours in almost 100% of animals[1]. HBsAg has been demonstrated on the surface and in the cytoplasm of PLC/PRF/5 cells using immunofluorescence techniques[1,3–5]. Recently, we reported that monoclonal antibodies to HBsAg (IgG1, IgG2a and IgM isotypes) bind to HBsAg-associated viral determinants of PLC/PRF/5 cells in culture and immunoprecipitate HBsAg secreted into the growth medium[6]. Also IgG2a and IgM antibodies to HBsAg (anti-HBs) produce specific lysis of PLC/PRF/5 cells in culture in the presence of complement, but have no lytic effect on human hepatoma cells which do not express HBsAg[6]. In the present study, we demonstrate that IgM and IgG2a, but not IgG1, monoclonal anti-HBs specifically prevent or suppress tumour formation in a substantial number of athymic nude mice injected with PLC/PRF/5 cells.

For immunotherapy, we used three anti-HBs producing hybridoma clones developed by Wands *et al.* which bind with high affinity and specificity to distinct viral determinants on HBsAg[7,8]. In preliminary experiments, we determined the dose required to maintain detectable levels of monoclonal anti-HBs in nude mouse serum. When 1×10^6 c.p.m. of ^{125}I-labelled monoclonal anti-HBs IgM (specific activity 7–10 μCi μg^{-1}) was injected intravenously (i.v.), 10,000–20,000 c.p.m. of ^{125}I anti-HBs per ml was present in nude mouse serum 3 days later. Following i.v. injection of 1×10^6 c.p.m. of ^{125}I anti-HBs IgM every 48 hours for 8 days, ^{125}I anti-HBs was detected in nude mouse serum 5 days after the last injection. Intraperitoneal (i.p.) injection of ^{125}I anti-HBs IgG1 or IgG2a produced similar levels of anti-HBs in nude mouse serum.

The effect of ascitic fluid containing anti-HBs hydridoma antibodies on production and growth of PLC/PRF/5 tumours was then determined. Treated BALB/c male nude mice received IgM anti-HBs (i.v.), IgG2a anti-HBs (i.p.), or IgG1 anti-HBs (i.p.), and control mice received 100 μl of phosphate-buffered saline (PBS) i.v. or i.p. Subcutaneous injection of PLC/PRF/5 cells produced tumours in 37/39 control nude mice (Table 1). Treatment of tumour-injected mice with anti-HBs IgM prevented tumour formation in 15/23 animals, and suppressed tumour growth in 4 others ($P<0.001$). Anti-HBs IgG2a showed a protective response in 18/26 animals, with prevention of tumour formation in 8 mice and suppression of tumour growth in 10 mice ($P<0.01$). Monoclonal IgG1 anti-HBs, which bound effectively to PLC/PRF/5 cells in culture[6], had no effect on tumour growth (Table 1). These results correlated well with our previous *in vitro* studies[6].

Two additional groups of animals were treated with monoclonal antibodies to non-HBV determinants. Ascitic fluid containing monoclonal IgM antibodies against influenza HA antigen[9] (i.v.) or IgG1–IgG2b monoclonal antibodies to tetanus toxin[10] (i.p.) showed an effect in that some treated mice did not develop PLC/PRF/5 tumours. However, no response was observed in 11/16 of these animals and once tumours became established during treatment with monoclonal anti-influenza HA protein or anti-tetanus toxin, there was no suppression of

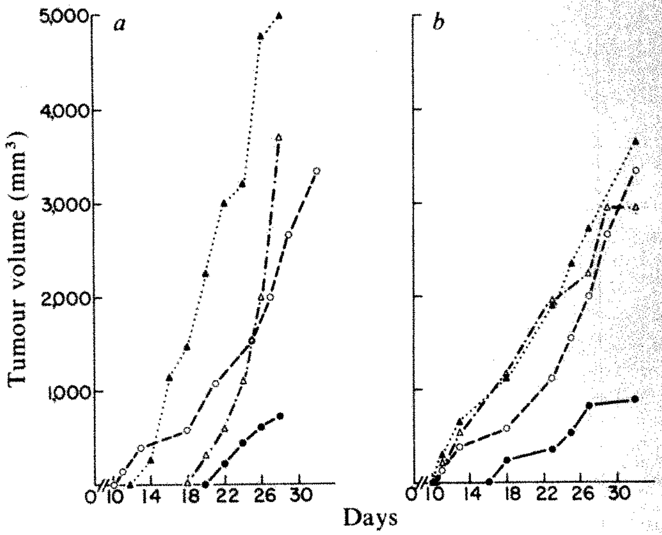

Fig. 1 Passive immunotherapy of PLC/PRF/5 human hepatoma with monoclonal antibodies to hepatitis B surface antigen. Four-to six-weeks-old male BALB/c *nu/nu* mice were injected subcutaneously with 10^7 PLC/PRF/5 cells on day 0. Mice were injected with 100 μl monoclonal antibodies to HBsAg IgM (i.v.) or with 100 μl anti-HBs IgG2a or IgG1 (i.p.). Control mice were injected either with 100 μl of monoclonal antibody to influenza HA antigen (i.v.) or with PBS (i.v. or i.p.). These data represent the results of one experiment in which all animals were injected with the same preparation of PLC/PRF/5 cells on the same day. Monoclonal antibody treatment was started within 1 h after tumour cell injection and was repeated every 48 h for 28–32 days. Mice were examined daily for tumour formation and the volume of palpable tumours was determined by a standard protocol with a calipers. The tumour volume is the mean of the maximal longitudinal diameter multiplied by the square of the maximal horizontal diameter. Numbers in parenthesis refer to the number of animals in each group. At the termination of experiments, tumours were excised and weighed, and mean weights of tumours in each group are expressed as mg per g mouse body weight. *a*, Treatment with monoclonal anti-HBs, IgM: ●, 'suppressed' tumours ($n=4$; tumour weight 6.2 ± 2.3 mg per g); ○, control tumours in untreated mice ($n=6$; 60 ± 25 mg); △, tumours in anti-influenza HA antigen treated mice ($n=4$; 60 ± 17 mg); and ▲, 'non-responder' tumour ($n=1$, 131 mg). *b*, Treatment with monoclonal anti-HBs, IgG2a or IgG1: ●, 'suppressed' tumours in mice treated with anti-HBs IgG2a ($n=9$; 10 ± 2.5 mg); △, 'non-responder' tumours in anti-HBs IgG1 treated mice ($n=9$; 56 ± 17 mg); ○, control tumours in untreated mice ($n=8$; 60 ± 25 mg); and ▲, 'non-responder' tumours in mice treated with anti-HBs IgG2a ($n=5$; 78 ± 33 mg).

0028–0836/82/310567—03$01.00

Table 1 Effect of monoclonal antibodies on tumorigenicity

Monoclonal antibody treatment	Effect on tumour growth Protective response	No response	*P*
None	2/39	37/39	—
Anti-HBs IgM (i.v.)	19/23	4/23	$P<0.001$
Anti-HBs IgG2a (i.p.)	18/26	8/26	$P<0.01$
Anti-HBs IgG1 (i.p.)	1/10	9/10	NS
Anti-influenza HA IgM (i.v.)	2/6	4/6	NS
Anti-tetanus toxin IgG1–IgG2b (i.p.)	3/10	7/10	NS

All mice were injected into the flank region with 1×10^7 PLC/PRF/5 cells on day 0, followed in one hour by injection of ascitic fluid containing monoclonal antibodies i.p. or i.v. as indicated, or PBS in animals not receiving monoclonal antibodies. The concentrations of anti-HBs in ascitic fluid were as follows: IgM clone 5D3, 5.6 mg ml^{-1}; IgG2a clone 5C3, 22.6 mg ml^{-1}; and IgG1 clone 2C6, 25.0 mg ml^{-1}. For anti-influenza HA antigen IgM and anti-tetanus toxin IgG1–IgG2b, the concentrations were 3.8 mg ml^{-1} and 10 mg ml^{-1}, respectively. 100 μl of ascites fluid containing IgM or IgG was administered every 48 hours i.v. or i.p., respectively. Nude mice tolerated repeated injection of ascitic fluid for up to 4 weeks (3% mortality compared to 2% in noninjected controls). Mice were killed within 28–33 days after tumour cell injection. Significance *P* was determined by comparing experimental mice to PBS treated controls, using the χ^2 test.

the tumour growth rate (see below). Thus, in animals receiving ascites fluid containing monoclonal anti-HBs IgM or IgG2a, there was a response in 27/49 animals, whereas in the combined groups treated with monoclonal anti-HBs IgG1, anti-influenza HA protein IgM or anti-tetanus toxin IgG1–IgG2b, there was a response in only 6/26 animals ($P<0.001$) which was not significantly different to control animals (2/39) with $0.05<P<0.1$.

Further evidence for suppression of tumour growth by monoclonal anti-HBs IgM or IgG2a was shown by an increased tumour latency (defined as the time from PLC/PRF/5 cell injection until the onset of gross tumour development), a slower tumour growth rate (determined by measurement of tumour volume) and a decreased tumour weight at necropsy compared to control animals. Figure 1 shows the latency and tumour growth rate in 46 nude mice injected with the same batch of PLC/PRF/5 cells and treated with various monoclonal antibodies. Most animals receiving monoclonal anti-HBs IgM did not develop tumours. In the four anti-HBs IgM-treated mice with suppressed tumour growth (Fig. 1*a*), latency was prolonged to 20–22 days as compared to 10 days in control animals. For reasons which are unclear, tumour latency was also prolonged to 16–18 days in anti-influenza HA IgM-treated mice. However, once tumours became established in anti-influenza HA protein-treated animals, their growth rate was most rapid (Fig. 1*a*). Tumour latency was also prolonged in IgG2a anti-HBs-treated mice (Fig. 1*b*). Mean tumour volume was decreased in IgM and IgG2a anti-HBs-treated mice with suppressed tumours (Fig. 1*a*, *b*) but was unchanged in mice treated with IgM monoclonal antibodies to anti-influenza HA protein (Fig. 1*a*). There was also no change in latency or tumour growth rate in IgG1 anti-HBs-treated mice (Fig. 1*b*). In animals with suppressed tumours, the mean tumour weight at termination of the experiment was reduced six- to tenfold (Fig. 1*a*, *b*). Tumour weight was unaffected in monoclonal anti-tetanus toxin-treated animals (data not shown). With one exception, when gross tumours did not develop following anti-HBs treatment, tumour cells were not identified histologically at the injection site.

In one anti-HBs IgM-treated mouse and five anti-HBs IgG2a-treated mice very large tumours developed (Fig. 1*a*, *b*). This 'escape' phenomenon, which has also been observed in other systems[11], was not due to inadequate monoclonal antibody treatment. HBsAg was completely neutralized in the serum of all anti-HBs-treated mice (Table 2), and HBs antigen was also identified in the medium cultured sublines established from three 'escape' tumours. Therefore, selection of non-HBsAg producing variants did not explain this phenomenon (our unpublished results).

The gross appearance of PLC/PRF/5 tumours in nude mice treated with IgM anti-HBs monoclonal antibody is shown in Fig. 2. An example of a mouse with a PLC/PRF/5 tumour in each category is illustrated; *a*, 'prevented', *b*, 'suppressed', *c*, control (untreated) and *d*, 'nonresponder' or 'escape'.

In the present study, the difference in effectiveness of IgG2a and IgM anti-HBs on PLC/PRF/5 tumour growth is not clear but may merely reflect the relatively small number of animals in each group. Although IgG2a anti-HBs can lyse PLC/PRF/5 cells *in vitro*[6] and was injected in a fivefold excess over IgM anti-HBs to reach comparable serum levels, it had primarily a suppressive rather than a preventive effect. This may be due to differences in the affinity or avidity of IgG2a and IgM monoclonal anti-HBs for HBsAg on the surface of PLC/PRF/5 cells or that these monoclonal antibodies recognize different HBsAg viral determinants[6–8]. Alternatively, mechanisms other than complement-mediated lysis may be involved in inhibition of tumour formation and growth in nude mice. To test this a panel of monoclonal antibodies of the same affinity and/or directed against the same or different viral epitopes of various isotopes would be useful. It is also possible that a combination of monoclonal antibodies directed against different viral epitopes might enhance effectiveness in suppressing or preventing PLC/PRF/5 tumour development.

Despite previous failures of polyspecific antisera in tumour immunotherapy[11], suppression of tumour growth in mice by monoclonal antibodies has been reported in mouse lymphoma[12] or leukaemia[13] and in solid tumours of human origin, such as malignant melanoma[14] and colorectal carcinoma[15]. A limited effect has also been observed recently in several patients with non-Hodgkins and T-cell lymphomas[16,17]. However, in some studies, monoclonal antibodies to tumour cell determinants have been shown to recognize more than one specific cell type[18–20], thereby limiting their potential effectiveness. The present experiments suggest that immunotherapy with monoclonal antibodies directed toward viral epitopes on HBsAg may alter the growth of a human hepatocellular carcinoma, when

Table 2 Detection of anti-HBs in the serum of PLC/PRF/5 tumour-bearing mice

Monoclonal antibody	No. of mice	Effect on tumour growth	Serum HBsAg and anti-HBs levels (c.p.m. ± s.e.) HBsAg	anti-HBs
None	8	None	9,910 ± 1,792	1,692 ± 439
Anti-HBs IgM	4	Suppressed	219 ± 25	29,239 ± 414
Anti-HBs IgM	7	Prevented	207 ± 15	28,816 ± 907
Anti-HBs IgM	1	Non-suppressed	179	28,144
Anti-HBs IgG2a	5	Suppressed	580 ± 243	19,178 ± 1,375
Anti-HBs IgG2a	5	Non-Suppressed	360 ± 46	19,893 ± 980
Anti-HBs IgG1	9	None	232 ± 17	21,368 ± 833
Anti-influenza HA antigen IgM	4	None	2,794* ± 656	639 ± 62

Mice were killed 28–32 days after tumour cell injection. HBsAg and anti-HBs were determined on the day of killing, using commercially available radioimmunoassay kits as previously described[1]. HBsAg in normal nude mouse serum was 252 ± 15 c.p.m. by RIA.

* IgM monoclonal antibodies to influenza HA antigen partially interfered with the RIA for detection of HBsAg.

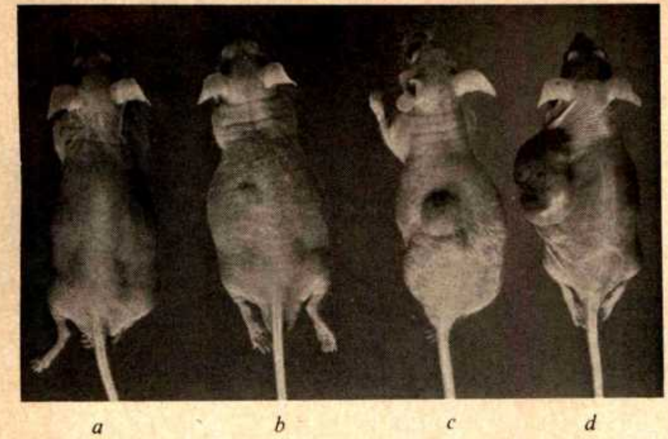

Fig. 2 Gross appearance of PLC/PRF/5 tumours in BALB/c nude mice receiving monoclonal IgM anti-HBs antibody treatment. BALB/c *nu/nu* mice were injected with 1× 10^7 PLC/PRF/5 cells and were treated with monoclonal anti-HBs IgM antibodies (i.v.) every other day, beginning 1 hour after tumour cell injection. This photograph was taken on the 28th day after PLC/PRF/5 cell injection. *a*, Tumour 'prevented'; *b*, tumour growth 'suppressed'; *c*, control tumour in untreated mouse; *d*, 'non-suppressed' or 'escape' tumour.

such viral determinants are expressed on the tumour cell surface. This study shows that a high affinity monoclonal antibody to a viral determinant can inhibit tumour growth and thereby overcome the problem of cross-reactivity with normal cell membrane constituents. While this approach might be applicable only in situations where specific viral proteins are expressed on the host cell surface, its potential use in heptatitis B virus carriers, especially in those patients with chronic liver disease, would seem possible.

We thank Drs B. R. Bloom, D. Rager Zisman and P. C. Quan for advice, Mrs E. Hurston for technical assistance and Dr W. Gerhard for the gift of H28-A2-1 cell line. The mechanism of tumour cell destruction by natural killer (NK) cells or other lymphocytes is not understood. NK cells appear to represent a primitive anti-tumour surveillance system more analogous to macrophages than lymphocytes[1]. Free oxygen radicals (O_2^-, OH) and H_2O_2 are thought to be involved in cell destruction by macrophages[2] and therefore we looked for similar cytocidal intermediates of oxygen in NK cells. These highly reactive molecular species can easily be detected in the presence of luminol by the emission of light[3]. We show here that highly enriched human NK cells respond to NK-sensitive but not NK-insensitive tumour cells with a rapid burst of oxygen metabolites as detected both by chemiluminescence and cytochrome *c* reduction. Agents which can prevent chemiluminescence and cytochrome *c* reduction, such as superoxide dismutase (SOD), reduced NK-mediated cytolysis and agents which increased chemiluminescence, such as interferon, also increased NK-mediated cytolysis. These results suggest that the production of oxygen species may be the earliest event to occur in the NK cell following tumour cell contact, and these products are involved in NK-mediated cytolysis.

Peripheral blood lymphocytes were depleted of monocytes and separated on a discontinuous Percoll density gradient[4]. Lymphocytes from the NK-enriched fraction were dark-adapted in the presence of luminol, to achieve a stable background, and then stimulated by the addition of tumour cells at a 10:1 tumour cell/lymphocyte ratio. As shown in Fig. 1, the addition of K562 cells (a human erythroleukaemia) caused a rapid increase in chemiluminescence, reaching a peak of 167×10^3 c.p.m. within 30 s followed by a rapid decline and a second peak of 120×10^3 c.p.m. at 3 min followed by a more gradual decline to low levels at 8 min. Parallel experiments using a cytochrome *c* reduction assay revealed rather slower kinetics with a reaction velocity of 200 pmol cytochrome *c* reduced per min per 10^6 Percoll fractionated cells. No further cytochrome *c* reduction occurred after 8 min, by which time the chemiluminescence response had returned almost to the background level. Addition of P815-2 cells (a murine mastocytoma) to Percoll fraction 2 cells caused a low chemiluminescence response (35×10^3 c.p.m.) and little cytochrome *c* reduction (<200 pmol) (Fig. 1). The area under the anti-P815-2 chemiluminescence curve was 36% of that under the anti-K562 curve. Addition of 100 μg (280 U) of SOD caused an 80–90% inhibition of both chemiluminescence and cytochrome *c* reduction. Even concentrations as low as 10 $\mu g\ ml^{-1}$ had a small but significant effect (data not shown).

To investigate the cells generating chemiluminescence, NK cells were enriched on a Percoll density gradient[4]. As shown in Fig. 2, there was a striking parallel between those fractions enriched in NK cytolytic activity and those fractions yielding the highest levels of chemiluminescence. In addition, Percoll fraction 2 cells reduced 210 pmol cytochrome *c* per min per

	α-Interferon (500 U ml^{-1}	120	NT	150	110
	α-Interferon + anti-interferon (1/50)	100	NT	110	105

Macrophage-depleted, peripheral blood lymphocytes were prepared and separated on Percoll density gradients as described in Fig. 2 legend. Each fraction was tested in a 2-h ^{51}Cr-release assay against K562 and the most active fraction (usually fraction 2) was treated as shown, and tested in parallel for (1) K562-stimulated chemiluminescence, calculated as the area under a 10-min curve (control values were 4–9 × 10^5 total counts); (2) cytochrome *c* reduction calculated as pmol cytochrome *c* reduced per min per 10^6 cells during the first 6 min of reaction (control values = 175–225); (3) cytolysis of K562 in a 4-h ^{51}Cr-release assay, calculated as lytic units at 20% lysis (control values were 8–16 × 10^2 lytic units per 10^7 cells); (4) the per cent fraction 2 cells binding to K562 cells in a single cell assay[19] (control values were 40–60%). All values are expressed as per cent control for ease of comparison. *a*, 2 × 10^6 fraction 2 cells were treated for 1 h at 0 °C with medium as control or 100 μg ml^{-1} (1/1,000 ascites fluid) of monoclonal, mouse anti-human NK antibody (HNK-1) (provided by T. Abo and C. Balch), washed and then treated for 1 h at 0 °C with 1/10 rabbit anti-mouse IgM (Cappel) (R anti-mIgM) followed by a 1-h treatment at 37 °C with 1/2 rabbit complement (C′) previously absorbed with human lymphocytes. *b*, 10^7 cells from various cell lines were added to fraction 2 cells. HEF, human embryonic fibroblasts; K562, human erythroleukaemia; clone B from K562 cultures induced to differentiate with sodium butyrate[13]; Chang, human hepatocarcinoma; and L5178Y, a lymphoma induced in DBA/2 mice with methylcholanthrene. *c*, K562 cells or Percoll fraction 2 cells were treated for 1 h at 37 °C with 0.2% glutaraldehyde and then mixed with unfixed effectors or targets respectively. K562 or P815 cells were also disrupted in a nitrogen bomb and plasma membrane vesicles were isolated on sucrose density gradients. The equivalent of 10^7 intact tumour cells (28 μg protein) were added to the effectors. *d*, Ten normal and four stably low NK responders were selected from a pool of 600 multiply tested, healthy donors, previously identified by Dr H. Pross. Cells from three Chediak-Higashi (CH) patients were provided by Drs L. Boxer and A. S. Fauci. *e*, Superoxide dismutase (Sigma, 2,800 U per mg protein), catalase (11,500 units per mg) and boiled (30 min) SOD as control was added to fraction 2 cells approximately 1 min before addition of K562. Cytotoxicity was measured in a 2-h assay. SOD activity was confirmed in a xanthine oxidase system[20]. *f*, Fraction 2 cells were preincubated for 30 min at 20 °C with 200 or 500 U human β-interferon (10^8 units per mg protein, provided by C. Tan) and α-interferon respectively. α-Interferon was incubated for 2 h at 4 °C with 1/50 monoclonal anti-human leukocyte interferon[21] (clone NK2; provided by Dr D. S. Secher) followed by 1/10 goat anti-mouse immunoglobulin. Precipitates were removed by centrifugation. Each experiment was repeated three times with similar results. NT, not tested.
